5.4 Bootstrap and Data Communication

Hitherto we discuss the process of slot allocation for controlling the medium access by the clients. We now describe how Whisper MAC manages client bootstrapping and data communication using the slot allocation. Client bootstrapping is a critical part of a TVWS based IoT network since it is required to comply with FCC regulations given the power constraint of the IoT devices. Recall that, each NB TVWS device must provide the WSDB its geo-coordinates and height to obtain the list of available channels for transmission at that location. Here, the clients can register via the gateway as they do not have Internet connectivity. Nevertheless, a key question remains. How does a client share its location with the gateway without knowing the available channel and time for transmitting registration request?

According to the FCC regulations, a client that is not registered in the WSDB can transmit only its location information or network join request on the channels registered against the gateway. To do so, a client requires to know the channels registered against the gateway where the list of these channels may even vary over time. As a remedy, Whisper MAC utilizes broadcast beacons that embed the info of join slots for clients to transmit WSDB registration, i.e., network join request. In the join slot, a client transmits the join request along with its location for WSDB registration and slot requirement for the data communication. Note that the beacon slots have predefined and fixed timing and channels. Therefore, the time synced (using GPS) clients can listen for the beacon frames without draining its power in random or continuous scanning. Figure 5 depicts an example scenario of client bootstrapping followed by data communication. Due to space limitations, we put the corresponding implementation details in Appendix B.5.

After receiving the WSDB registration response, i.e., join response, a client is ready for the data transmission in the allocated slots (piggybacked as MAC command in the response frame) until the expiry of channel. A TVWS device is required to contact (poll) the WSDB once every 24 hours and check the list of available channels at the location. The poll request is piggybacked as a MAC command in a confirmed-up data frame. The expiry generally gets extended after the polling, and updated expiry is sent in the downlink ACK. However, polling is not required for a client generating event-driven traffic as it freshly joins the network whenever it has a data frame to transmit.

6 Dynamic Spectrum Access

The dynamic nature of TVWS spectrum can lead to bottlenecks when it is utilized for NB IoT networks. First, the long distance between the gateway and a client brings about separate uplink and downlink having dissimilar quality at their corresponding locations. Second, the IoT clients are power
Figure 6: Block diagram of our spectrum sensing module that measures interference from the incumbent users.

constrained. Hence, any extra transmission and carrier sensing activity by the clients for spectrum management adds power overhead. Whisper addresses these challenges by implementing spectrum awareness capability and then incorporating smart spectrum exploitation approach in the protocol.

6.1 Spectrum awareness

Uplink communication is inevitably significant in most of the IoT applications as IoT traffic is push-based. The quality of this communication link directly relies on the interference nearby the gateway. Hence, we first try to enable spectrum awareness at the gateway. A part of spectrum awareness, both uplink and downlink, is achieved by using the WSDB. However, it is not enough to accumulate info about the real-time activity of incumbent users – both licensed and unlicensed – in the carrier. To do so, Whisper performs spectrum sensing.

First off, how can the interference level in a NB channel be measured given the Whisper radio uses LoRa modulation and its minimum detectable signal (MDS) is very low (-149 dBm)? The LoRa modulation enables frame reception even when the carrier signal level is below the ambient RF noise floor. Consequently, the conventional approach of measuring RF energy in a NB channel as an indication of interference level is not viable here. Instead, we design a custom off-the-shelf spectrum sensing module to evaluate the level of interference in NB TVWS channels. It can evaluate the impact of interference from licensed and unlicensed cognitive radio users at a very low signal level.

Spectrum sensing module locally generates RF signal with a controlled amplitude to determine MDS in a NB channel. The MDS gives the perception of interference from incumbent users in the NB channel – a lower MDS implies a lower RF interference. Figure 6 depicts the block diagram of the spectrum sensing module. It consists of a transmitter, a controlled attenuator, an RF combiner, and a receiver. We use two Whisper radios as the transmitter and receiver. The attenuator is controlled by the transmitter. We modify transmitter radio firmware to set the value of attenuator. To estimate the MDS in a channel, we tune the transmitter and receiver to the specific channel frequency, and the transmitter starts transmitting test frames. The RF signal of a test frame is attenuated by the attenuator to yield a weak signal similar to a reception from a remote transmitter, which is a commonly practised technique in laboratory emulation [15]. The combiner combines this weak signal with the ambient RF signals (includes interfer-

ence from incumbent users) picked up by the antenna. The attenuator value is varied to identify the maximum attenuation that results in 90% successful frame reception. The lowest RSSI of the received frames is the MDS under the interference. Note that the spectrum sensing module only senses the RF channel. The generated RF signal is only used internally, and thus has no effect on data communication and channel occupancy limit. The spectrum sensing module is a part of the gateway as mentioned in Section 4. The channel control unit utilizes it every hour to update the interference level from the incumbent users.

6.2 Spectrum exploitation

The interference in the downlink at the location of a client cannot be measured with the spectrum sensing module, given the long distance. Furthermore, carrier sensing at the client's end would add huge power overhead. Here, Whisper enables the spectrum exploitation approach to mitigate the effect of interference through dynamic channel assignment that does not require any additional frame transmission.

Before jumping into the details, we first introduce the related terminologies and notations. For each slot, we define a channel-tube (ChT) that has two channels for a confirmed-up and one channel for an unconfirmed-up data frame. For a slot used in periodic traffic, N_{ChT} channel-tubes are assigned by adjusting the A_c for the associated channels during the slot allocation described in Section 5. In every occurrence of the slot, a ChT is picked in a sequential round-robin manner for communication. In case of event-driven traffic, a ChT is assigned which is different from last $(N_{ChT} - 1)$ ChTs. In this way, when a slot completes hopping across all N_{ChT} ChTs, we call it a hopping cycle. Note that, a client may have multiple slots (as mentioned in Section 5) and each slot has an individual set of N_{ChT} ChTs. Furthermore, ChTs are preferably selected from different TV channels to facilitate robustness against broadband interference. Next, we delineate how the set of ChT is dynamically updated in three phases.

1. Monitoring phase: During this phase, the performance of assigned ChTs for all the slots of a client is monitored at the gateway, and a flag is raised in case of substandard performance. It is raised based on the overflow of a bucket that is filled up with the tickets for an event of missing frame in a ChT. The number of tickets for a missing event is equal to the number of previous consecutive occurrences starting from the current event in the ChT. In the event of successful communication in a ChT, we remove its tickets in a similar manner. Now, how do we detect an incident of the missing frame? We here leverage the frame count block of the standard LoRaWAN frame header. Finally, we need to determine the optimal bucket size (S_{bukt}). It is directly related to $\sum_{i=1}^{ND_{ChT}} k_i$ where ND_{ChT} is number of distinct ChTs and k is number of times it is used in a cycle. S_{bukt} depends on the length of hopping cycle too. For example, a client with a smaller cycle

overflows the bucket faster in presence of a short-term interference, whereas it gets slower in case of a longer cycle with long-term interference. Both these scenarios are undesired. Here, we express S_{bukt} as $m\sum_{i=1}^{ND_{ChT}} k_i$ for different bands of cycle. From our emulation and real-world deployments, we found the following optimal values of m with $N_{ChT} = 4$ for each slot. Here, m typically exhibits an exponential downward pattern with respect to the length of cycle.

$$m = \begin{cases} 2.5, & \text{cycle length} < 1hr \\ 1.6, & 1hr \leq \text{cycle length} < 3hr \\ 1.05, & 3hr \leq \text{cycle length} < 6hr \\ 0.7, & 6hr \leq \text{cycle length} < 11hr \\ 0.5, & 11hr \leq \text{cycle length} \end{cases}$$

2. Decision making phase: After a flag has been raised, the decision making phase decides which ChT and associated channels are to be replaced. We note that a ChT is selected for replacement if its contribution in bucket overflow is at least a certain percentage defined as, $\frac{k_i}{\sum_{i=1}^{ND_{ChT}} k_i}$. If no such ChT is found, older events are removed to accommodate new events in the bucket. Next, we find which channel(s) in the ChT(s) needs to be replaced based on the knowledge from the monitoring phase. The replacement ChT is placed exactly at the same sequential position of the replaced one in the current list of ChTs for a slot.

3. Execution phase: For a client sending confirmed-up frames, the execution of ChT update is initiated immediately after the decision making. Whereas, in case of a client sending unconfirmed-up data frames, it is carried out when the client polls the channel from WSDB since this is the only time when the client sends confirmed-up data frames. The execution is initiated by the gateway by sending an update notice in the downlink frame. The client sends a notification of notice reception in the following uplink data frame. To ensure the robustness against frame loss, the update notice (if a confirmed up frame is received) and notification are sent in the following N_{ChT} slots. The timing of the update is set accordingly in the notice. Note that the execution process is separate for each slot. Furthermore, no extra frame is exchanged for the execution process since all the associated MAC commands are piggybacked in the data frames.

6.3 Fallback

Finally, in a rare event of complete communication loss with the gateway, a client calls for the fallback. Although a client sending confirmed-up data frames detects such an event straight away, a client sending unconfirmed-up data frames detects only at the time of channel polling from WSDB. In such an event, the client does not get a downlink packet in any slot and ChT. As a fallback alternative, the client rejoins the network. It reports the event in the join request so that gateway can assign a different set of ChTs.

	Avg.	Max	Min
Throughput (in bps)	0.0626	0.0681	0.0601
FDR (in %)	98.4	100	97.1
Latency (in sec)	2.39	2.43	2.37

Table 2: Performance of Whisper in real-world deployment

7 Evaluation

In this section, we focus on evaluating the performance of Whisper through a real-world deployment and simulation. We further make a comparison with the ISM band IoT solutions.

7.1 Real-world deployment

We have an ongoing deployment of Whisper on 8500 acre dry-land wheat farm in Eastern Washington, which has been operating for over 2.5 months. Here, Whisper is used by the third-party users in collecting sensor data from 17 different fields for multiple data-driven agriculture applications.

7.1.1 Setup

The deployment includes 20 Whisper client radios that communicate with a single gateway. The client radios are retrofitted inside a weatherproof box, powered by solar, and connected to a sensor interface to collect data from five sensors – temperature, humidity, CO_2, and soil moisture and temperature (Figure 7b). As configured by third-party users, 11 clients report data of all sensors at different periodicity starting from 30 min to 12hr. Similarly, the remaining clients report all sensor data in an event-driven manner based on CO_2 level. All of the data frames are confirmed-up – 51 bytes uplink, 20 bytes downlink. The modulation parameters are configured to have a coding rate (CR) of 4, 62.5 kHz channel bandwidth (ChBW), and preamble length of 8. We tune the spreading factor (SF) based on the distance of the clients from the gateway as shown in Figure 7c.

The gateway is deployed on the farm, and due to a lack of power, is powered by solar power (Figure 7a). Since there is no Internet connectivity in the middle of the farm, we use an Adaptrum TVWS broadband radio at the gateway to create a wireless link to the nearest source of connectivity (farmer's home) [2]. It in turn enables the evaluation of Whisper in coexistence with off-the-shelf unlicensed TVWS broadband network. We use a Raspberry Pi 3B as the edge device at the gateway. For WSDB, we use Wave DB Connect by RED Technologies [31]. Finally, both BS radio and clients use omnidirectional antennas with approximately 5 dBi gain where the TX power is set to the max according to Section 3.

7.1.2 Results

Thus far, 4766 sensor data points have been collected via Whisper. We evaluate the performance of Whisper in terms of three metrics: throughput, frame delivery ratio (FDR), and
Figure 7: Whisper Deployment. The solar powered IoT Hub shown in (a) includes a broadband TVWS backhaul and Whisper gateway. In (b), Whisper client integrated with sensors and retrofitted inside a weatherproof box. (c) shows the deployment map.

Figure 8: (a) Range of Whisper radio and (b) Comparison of energy consumption between Whisper radio in TVWS VHF band and off-the-shelf LoRa radio in ISM band.

latency. The value of each metric is averaged over a period of 24hr. We do not observe any significant deviation in the average values of these metrics throughout the deployment period. Table 2 summarizes the results. We also observe that Whisper has shown robustness against multiple real-world incidents such as power outages at gateway and clients due to thunderstorms, disrupted Internet connectivity, and WSDB disruption due to maintenance. Furthermore, Whisper shares the spectrum (470 to 488 MHz) with Adaptrum broadband TVWS radio in the deployment as we mentioned above. However, we do not observe any mutual interruption in the communication of Adaptrum radio and Whisper.

7.1.3 Range

We perform range experiments to evaluate the sensitivity of the Whisper radio. Range tests are conducted in both urban and rural environments, where both have line-of-site (LOS) and non-line-of-sight (NLOS) connectivity. For the urban settings, we place a BS radio on the rooftop of an industry campus building. Then, we move the client to different locations using a vehicle and record the RSSI. The radios are configured for LoRa modulation having a ChBW of 31.25 kHz, SF of 12, and CR of 4 in the VHF band. Figure 8a shows the RSSI of received frames with respect to distance in miles. We can see that frames are successfully received at 11.3 miles with RSSI of -85 dBm. For the evaluation in rural settings, we use our aforementioned farm deployment. In this scenario, the performance is even better in comparison to the urban settings. We can see that packets are successfully received at

15 miles with a measured RSSI of -87 dBm which is significantly higher than the MDS (-149 dBm) of Whisper radio. These results imply that clients can be deployed as far as 15 miles away from the gateway, and likely even further. For example, in Figure 7c, one of the clients communicates with the gateway from a distance of 18.5 miles. Note that, the range of LoRa in ISM band is found to be 1 - 3 miles in literature and our real-world deployment [4].

7.1.4 Energy profile

We next conduct energy profiling of Whisper radio operating in TVWS spectrum and compare it with an off-the-shelf LoRa radio, SX126xMB2xAS [20], operating in the US915 ISM band. The physical setup for the experimentation is similar to the range test. Both radios are configured to send an uplink frame of 51 bytes every hour to the gateway with the same LoRa modulation configurations (CR: 1, ChBW: 62.5 kHz, TX power: 20 dBm). We then vary the distance of the radios from the gateway and tune the SF accordingly for successful communication. In Figure 8b, we show the energy consumption for each frame transmission in TVWS VHF band (174.3 MHz) and ISM band (915 MHz). Note that the energy consumption of the Whisper radio in locking GPS (once in 24hr) is prorated over its transmitted frames. Up to the initial distance of around a mile, the energy consumption in the TVWS spectrum is higher. However, as the distance increases, the time on the air for frame transmitted in the ISM band increases due to the higher spreading factor. Whereas, the lower frequency of the VHF band facilitates longer distance with comparatively lower SF. Consequently, the energy consumption becomes at least 2x higher in the ISM band compared to the TVWS VHF band after a mile of distance.

7.1.5 Performance in presence of interference

To evaluate the performance of Whisper under interference in the above-mentioned real-world deployment, we create interference with a separate transmitter. The interference is introduced on both uplink and downlink channels in three different ways - intermittent, continuous, and complete block.
Figure 9: Whisper's response to different types of interference on (a) downlink and (b) uplink channels in real-world.

In the case of intermittent interference, the interferer hops across the channels of $N_{ChT} = 4$ *ChT*s and creates short-term interference for the period equals to the time on air of a frame. Whereas, in continuous interference, the interferer picks one of the channels from the 4 *ChT*s and creates continuous interference on that channel. Finally, in case of complete block, the interferer is time-synced and aware of the hoping cycle schedule of the target radio. It accordingly creates interference on the active channel for data communication.

We evaluate the impact of these three types of interference on downlink channels. The interferer is placed very close to a client with high transmit power. The interferer is aware of the downlink channels used by the client. We then record the FDR on the downlink channels and the activity of switching channels for the client. In this way, we investigate the impact of interference for the clients, having different periodicity and traffic patterns, in our aforementioned deployment. Since all the clients generating periodic traffic exhibit similar behavior, we only discuss a client having a periodicity of 30 min. Figure 9a shows downlink FDR of the client averaged over a period of 120 min (one hopping cycle). As shown in the figure, the intermittent interference has a very minor impact on the FDR. No *ChT* update is initiated in response, whereas, for continuous interference, we observe a significant drop in FDR after the interferer is activated (point A in Figure 9a). As a result, a *ChT* update is initiated by the gateway. After the execution of same, the FDR reaches 100% (point C in Figure 9a). Finally, for complete block interference, we see the complete cease in downlink communication for the client. Consequently, the client triggers the fallback mechanism and rejoins the network (point B in Figure 9a). As a new set of *ChT*s is assigned after rejoining, the FDR reaches the maximum. We observe a similar impact of intermittent interference and a lesser impact of continuous interference on clients generating event-driven traffic. This is due to the members of the set of 4 *ChT*s varying with time. Nevertheless, it is difficult to create complete block interference for event-driven traffic.

Next, we evaluate the impact on uplink channels by placing the interferer close to the gateway. We select four uplink channels of the same client for the interferer, however, these channels are used by more than half of the clients in different combinations. To get a precise understanding of the effect of interference, we record uplink frames transmitted by any client on only these four channels. Figure 9b shows corresponding uplink FDR averaged over a period of 120 min. We

observe very minimal effect of the intermittent interference on the network and no *ChT* update took place for the same. In case of continuous interference, we see a drop in the FDR after the activation of interferer (point A in Figure 9b). Over the period of two days, *ChT*s of two clients are updated followed by increment in FDR (point C and D). Besides, the spectrum sensing unit detects the interference on the channel, and consequently, the channel is not further assigned to any client for sending event-driven traffic in this period by the channel coordinator. Finally, the complete block interference only affects the communication of one client. The client exhibits similar response as described above in case of the downlink.

7.2 Simulation

We now focus on evaluating Whisper's capability in terms of scale. Since deploying a very large-scale network (100s of clients) is challenging, we carry out the simulation. In particular, we evaluate two things: (1) how the larger bandwidth of TVWS spectrum facilitates scaling and (2) how Whisper MAC makes better utilization of this bandwidth compared to mainstream IoT MAC protocols. For this purpose, IoT devices transmitting images is a compelling application scenario (Section 2). We simulate this scenario in three network setups: (S1) Whisper MAC in TVWS spectrum, (S2) Whisper MAC in ISM band, and (S3) pure ALOHA (used by LoRaWAN) in TVWS spectrum. Comparison between S1 and S2 shows the role of bandwidth in our application scenario, whereas S1 and S3 show how Whisper MAC makes better utilization of this larger bandwidth.

7.2.1 Setup

We first integrate the LoRa physical layer from FLoRa simulator and the simulation environment of OMNet++ with our protocol [29]. We set up a single-gateway star-topology network where every IoT client device sends a 25 kB image. The gateway has eight BS radios. The number of clients is varied from 5 to 1000 at an increment of 5. The ratio of clients generating periodic traffic (N_p) to event-driven traffic (N_e) is also adjusted in five levels. We make an even distribution of image generation periodicity starting from 1hr to 24hr among the clients generating periodic traffic. A client with event-driven traffic sends an image once in every 24hr following random distribution. For S1 and S3, the uplink frame size is 255 bytes and downlink ACK frame is 18 bytes. The LoRa modulation parameters are set as following - CR: 1 and ChBW: 62.5 kHz. To simulate the effect of distance and associated data rates, we make an even distribution of six possible SF values ($7 - 12$) among the clients. Beacon periods are separated by two minutes with a periodicity of $p_{bcn} = 1$hr (Appendix B.5). For simulation purposes, since radios are not certified real devices, we use a local proxy of WSDB where each device, including gateway, has 3 TV channels available for transmis-

(a) Throughput

(b) Frame delivery ratio

(c) Image Transfer Time

Figure 10: Simulation results showing the role of large TVWS band and how Whisper MAC better utilizes the same in scaling.

sion. For S2, we use the four uplink data rates, DR0-DR3, permitted in the US915 ISM band where corresponding SF ranges from 10 to 7 with the channel bandwidth of 125 kHz. The dwell time restriction limits the uplink payload size (in bytes) for these data rates – DR0:11, DR1:53, DR2:125, and DR3:242. On the downlink side, we use data rates, DR10-DR13, having same SFs as uplink with ChBW of 500 kHz.

7.2.2 Results

We analyze the performance in terms of throughput, FDR, and image transfer completion time.

1. Throughput: As shown in Figure 10a, we analyze the throughput of the network under a various number of clients and ratios of traffic types. Each point in the graph represents the average throughput of the network in a period of 24hr. Here, we only consider the data frames, not any frames associated with the bootstrapping process. For S1 (Whisper in TVWS), the throughput increases linearly with the number of clients for every ratio of traffic types ($N_p : N_e$) until it reaches the network capacity. As the proportion of event-driven traffic increases in a group of clients, the throughput slightly drops due to the higher collision rate among the randomly triggered events. For S2 (Whisper in ISM band) and S3 (ALOHA in TVWS), we only show the representative results from the traffic ratio of 50 : 50. Although S2 shows similar patterns as S1, there are two distinct factors. First, due to the limited bandwidth in ISM band compared to the TVWS spectrum, S2 reaches the saturation point with ∼ 5x fewer clients than S1. Second, for the same number of clients in the network, S2 exhibits higher throughput as per-channel bandwidth is higher and supported SF is lower in the US915 ISM band compared to the TVWS spectrum. However, the lower value of supported SFs in the ISM band results in a much shorter range. In case of S3, both maximum throughput and number of supported clients are significantly lower than S1. This shows why the existing mainstream IoT MAC protocol is not suited for making better utilization of large TVWS bandwidth.

2. FDR: In computing FDR, we consider the frame generated but not successfully transmitted, even due to implied silence by Whisper MAC, as a frame loss. Figure 10b provides similar insights as the throughput. Although the initial throughput is found higher in S2 than S1, FDR is lower in the ISM band due to the larger number of small frame (both uplink and downlink) transmission for sending each image

(Section 2). It, in turn, increases the probability of frame loss.

3. Image transfer completion time: We further report the time required to send an image including the re-transmission of frames. The image is dropped after 3hr, if it is not completely transmitted. As shown in Figure 10c, the completion time linearly increases for S1 and S2 until it hits the saturation point, whereas it increases exponentially for S3. Now, although S2 exhibits higher throughput than S1 at the cost of a much shorter range, S2 reports at least 2x higher completion time. Because, in ISM band, a client requires to transmit a larger number of small frames to send an image due to the cap on uplink payload size (Section 2).

8 Related Work

Even though unlicensed operations in TVWS spectrum have been extensively studied in literature [5,6,21]. Nearly all prior work have focused on broadband scenarios and corresponding FCC regulations. However, there are fundamental differences in NB operation such as power constraint of IoT devices, number of devices in the network, channel occupancy limitation, etc. These make the challenges in unlicensed NB operation non-trivial to solve. There are some prior work on devising suitable signal modulation techniques for NB operation in TVWS spectrum [25, 27, 28]. However, dynamic spectrum access and management in NB operation, compliance with the NB FCC regulations, and corresponding comprehensive MAC protocol design are beyond the scope of these work.

9 Conclusion

In this paper, we have presented Whisper, a new solution to enable long-range and wider spectrum communication for IoT by leveraging TVWS spectrum. With Whisper, we get at least 5x longer range compared to LoRa operating in ISM band. Consequently, in our real-world deployment, Whisper has covered 17 fields in a 8500 acre farm with single gateway. Besides, the lower frequency of TVWS spectrum facilitates 2x less energy consumption than ISM band at a range of more than a mile. Note that, for a deployment spanning not more than a mile from the gateway, LoRa in ISM band would be preferable over TVWS spectrum. It also holds for an indoor scenario. Finally, with only 3 white TV channels, Whisper can accommodate 5x more traffic than ISM band.

A Compliance of Emission

We conduct laboratory measurements to ensure that the emission generated by Whisper radio complies with the FCC leakage regulations. Our evaluation is twofold. First, we look at the changes in the desired to undesired (D/U) signal ratio on the first adjacent channel of select DTV receivers when the source of the undesired signal is changed from a broadband white space device (WSD) to a NB WSD (Whisper radio). Second, we evaluate the changes in the D/U ratio on the first adjacent channel of select DTV receivers in response to the airtime of Whisper radio.

A.1 Setup

As the bandwidth of a NB TVWS channel is limited to 100 kHz, we select the lowest and highest possible bandwidths supported by the Whisper radio within the limit. Recall that airtime in LoRa modulation is determined by the spreading factor (SF). In this case, we use the lowest (SF7) and highest (SF12) possible spreading factors to change the airtime from low to high, respectively. The duty cycle of the Whisper IoT radio was set at 78% (ON time 780 ms, OFF time 220 ms for each second transmission). Note that the FCC proposed duty cycle is considerably less: 1%.

As shown in Table 3, a set of DTVR - RX1, RX4, RX5, RX10, and RX12 - are identified for this evaluation to diversify over different price ranges, resolutions, dimensions, and form factors. Channel 9 in the high-VHF band (center frequency: 189 MHz) and Channel 16 in the UHF band (center frequency: 485 MHz) are selected to provide the desired DTV signal. The D/U ratio for the Whisper radio is average across four desired signal levels – moderately strong (-43 dBm), moderate (-53 dBm), moderately weak (-65 dBm), and very weak (-80 dBm) at ± 3 MHz and ± 6 MHz from the edge of the broadcast DTV channel. These are the same desired signal levels used in the broadband WSD laboratory testing. In this way, the two sets of measurements for the D/U ratio on the first adjacent channel can be compared. The video loop used in the D/U measurements for the broadband WSD measurements is used for this test. For each measurement, the undesired signal power is increased until artifacts are observed.

A.2 Results

Table 4 and 5 summarize the results of D/U ratio evaluation for different DTVR receivers.

For the ATSC 1.0 DTVs, (RX1, RX4, RX5, and RX10), the D/U ratio on the first adjacent channel for the NB TVWS IoT radio indicates the receivers are even more selective (i.e., the value of the D/U ratio more negative) with respect to an undesired NB WSD than an undesired broadband WSD. Note that the D/U ratio at ± 6 MHz from the broadcast channel's edge is usually a few dB better (more selective) than the D/U ratio at ± 3 MHz from the broadcast channel's edge.

For the ATSC 3.0 receiver (RX12) tests at a modulation level of 256QAM, the D/U ratio for NB and broadband WSDs for moderate and weak desired signals are about the same, within error. There is a 5-6 dB difference for moderately strong and very weak desired signal, where the NB WSD is more selective than the broadband WSD for moderately strong signals and the NB WSD is less selective than the broadband WSD for very weak signals. In both instances, the D/U ratio represents very high ATSC 3.0 receiver selectivity. As RX12 is tested only at 256 QAM, it could be a function of the higher threshold at this modulation level.

DTVR ID	Manufacturer	Model	Standard	Profile	Resolution	Display size
RX1	Samsung	UN65NU8000	ATSC1.0	TV	4K	65in
RX4	Samsung	UN32N5300AFXZA	ATSC1.0	TV	1080p	32in
RX5	Insignia	NS-24DF310NA19	ATSC1.0	TV	720p	32in
RX10	Mediasonic	HOMEWORX HW130STB	ATSC1.0	Set-up box	1080p	-
RX12	RedZone	TVXPLORER BUNDLE	ATSC3.0	USB dongle	HD	-

Table 3: Information of DTVR receivers

DTV center frequency = 189MHz (Channel 9)			
	Change in D/U when SF is increased from SF7 to SF12		Change in D/U when b/w is increased from 7.8kHz to 62.5 kHz
DTV Receiver	7.8kHz	62.5kHz	SF7	SF12
RX1	-0.1	1.4	1.8	0.3
RX4	0.9	1.4	0.8	0.3
RX5	0.1	1.2	1.5	0.4
RX10	0.1	8.1	8.0	0.0
RX12	0.5	2.5	3.1	0.2

Table 4: Change in the D/U Ratio of DTV Receivers for the DTV Transmitter Operating on Channel 9

DTV center frequency = 485MHz (Channel 16)			
	Change in D/U when SF is increased from SF7 to SF12		Change in D/U when b/w is increased from 7.8kHz to 62.5 kHz
DTV Receiver	7.8kHz	62.5kHz	SF7	SF12
RX1	-0.2	1.7	1.9	0.0
RX4	0.6	1.0	0.6	0.2
RX5	0.1	0.7	1.0	0.2
RX10	0.1	4.7	5.0	0.2
RX12	0.3	1.1	1.3	0.0

Table 5: Change in the D/U Ratio of DTV Receivers for the DTV Transmitter Operating on Channel 16

In general, the NB WSD operating at 62.5 kHz bandwidth with a spreading factor of SF12 displays higher impact on DTVR operation compared to other configurations. For the traditional ATSC 1.0 DTV receivers (RX1, RX4, and RX5), there is negligible change in the D/U ratio for the NB WSD operating at bandwidths of 7.8 kHz (at spreading factors SF7 and SF12) and 62.5 kHz (at spreading factors SF7 and SF12), for measurements in both the UHF and high-VHF bands. For the low-cost digital-to-digital converter (RX10), there is significant change in the D/U ratio with the 62.5 kHz bandwidth and SF12, with a greater change observed in the high-VHF band than the UHF band. For the ATSC 3.0 receiver, there was a $2-3$ dB change in the D/U ratio observed in the high-VHF frequency band for the 62.5 kHz bandwidth and SF12. The change in the UHF frequency band was minimal: $1.1 - 1.3$ dB.

B   MAC Protocol

B.1   Handling collision in quantum selection

If two assignments – A_1 and A_2 – of a scheduling quantum are colliding, we can make these collision free by ensuring that one of these keeps silence in the colliding hour. For example, if A_2 keeps silence, then we represent collision free

form of it as $A_2 < h_{s2}, p_2, Silent[<h_{s1}, p_1>]>$. Inside $Silent[]$, we can keep all the assignments colliding with A_2. In this way, the new assignment is made collision free with respect to the existing assignments of a quantum. Now, the question arises, how to measure the effect of silencing? Here, we introduce a new metric, frequency of silence (ω_q), representing how frequently the new assignment requires to be silent. We can get the value of ω_q from the generic form of solution to Diophantine equation. In the aforementioned example, ω_q for A_2 is quotient of p_1 divided by $gcd(p_1, p_2)$. If $\omega_q = 1$, then the new assignment requires to be silent in every occurrence of it to avoid collision. Consequently, the quantum is of no use for the new assignment. Based on it, if the quantum has existing assignments (mutually non-colliding by definition) that collide with the new one, we use $\omega_{q\%} = \frac{number\, of\, assignments\, impelling\, \omega_q\, frequency\, of\, silence}{\omega}$ for quantum selection. If $\omega_{q\%} \geq 1$, then the new assignment requires to be silent in every occurrence of it. Note that the value of $\omega_{q\%}$ is clamped at 1 for any further calculation.

B.2   Construction of channel occupancy table

In Figure 4, A_{c0} is the first assignment for the channel with the occupancy of $\tau = 6$. The first table in the figure represents the entry of A_{c0}. The first entry in the table with no assignment is to facilitate future entries. A_{c1} is the next assignment with the occupancy of $\tau = 9$ and does not collide with A_{c0}. Now, there are 2^2 possible combination of these two assignments as shown in the second table which is basically a binary counter of two digits. However, A_{c0} and A_{c1} do not collide, and thus the last entry in the second table has $\tau = 0$. Consequently, any combination in future having these two assignments will not have a common colliding hour. So we can remove this entry and get the third table. A_{c2} is the next assignment with the occupancy of $\tau = 12$ and collides with both A_{c0} and A_{c1}. Using the method of binary counting we derive the fourth table from the third one. Finally, if the value of τ crosses the limit of $36sec$ in an entry while adding a new assignment, the assignment is not valid for the channel.

B.3   Pseudo code of slot allocation algorithm

In Algorithm 1, we show how possible combinations of slots are prepared. We first get the dictionary of collision free scheduling quanta for all base station radios using scheduling quantum selection as mentioned above. The output of

Algorithm 1: Pseudo code: Generate possible combination of slots for slot allocation algorithm

```
Function Get_PossibleSlotCombinations(p, σ, αmin):
    GET qDictionary FROM Quantum_Selection(p);
    INIT possibleSlotCmbntns[] TO empty;
    while qDictionary != empty do
        POP entry<A, collisionFreeq[]> FROM
          qDictionary;
        for α = αmax TO αmin do
            if collisionFreeq != empty then
                INIT listOfGrpdq[] TO (SELECT * FROM
                  (SELECT * FROM collisionFreeq GROUPBY
                  (continuity = α)) ORDERBY (AVG(ρq));
                INIT cntGrpdq TO Count(listOfGrpdq);
                INIT numOfSlotRqrd TO ⌈σ/α⌉;
                INIT cntSlotGotChnl TO zero;
                INIT slotsWithChnl[] TO empty;
                for i = 0 TO cntGrpdq − 1 do
                    INIT Ac TO <A, τ, listOfGrpdq[i]>;
                    GET channel FROM Channel_Selection (Ac);
                    if channel != null then
                        ADD <listOfGrpdq[i], channel> TO
                          slotsWithChnl[];
                        INCREASE cntSlotGotChnl BY 1;
                        if cntSlotGotChnl == numOfSlotRqrd then
                            ADD <slotsWithChnl[], α, Avg(ρq), ρc, A>
                              TO possibleSlotCmbntns[];
                            break;
```

scheduling quantum selection is a dictionary having different possible (with(/out) modification for silencing) assignments ($A<h_s, p, Silent[]>$) as the key and corresponding list of collision free scheduling quanta as the value. For each entry in the dictionary, we then vary the continuity (α) of the scheduling quantum from max to given min. For each continuity value, we group the α consecutive scheduling quanta. Groups are ordered by the average ρ_q of member scheduling quanta in each group. Here, to serve the requirement of σ scheduling quanta, we take $\lceil \frac{\sigma}{\alpha} \rceil$ groups of scheduling quantum. Next, we select downlink channel for each group using the channel selection algorithm. Now, each group is an individual slot, and the combination of $\lceil \frac{\sigma}{\alpha} \rceil$ slots together satisfy the requirement from the client. In this way, we make a list of the possible combinations of slots. Next, to select a combination from the list, we use the above mentioned weight function.

B.4   Cases where *p* is out of boundary

Now, what if the traffic has a periodicity of p_{low} seconds that is less than 1hr? We convert it as $\lceil \frac{p_{low}}{3600} \rceil$ requirements hav-

ing a periodicity of 1hr. During the slot allocation, we select slot combinations for each requirement having a time gap of no more than p_{low} seconds from the selected slot combinations for earlier requirement. If a client generates periodic traffic with $p > 24hr$, it freshly joins the network before data transmission. Because as mentioned in Section 5.4, a static client with periodic traffic requires to poll channel status from WSDB once in every 24 hours with the recent GPS reading. The poll request is piggybacked as a MAC command in a confirmed up data frame. As a client generating traffic at a periodicity of more than 24hr, it does not send any data frame within 24hr of the pervious one where the poll request can be piggybacked. Besides, sending a frame just for channel polling would be power inefficient. Thus, it it freshly joins the network every time when it has data frame to transmit. It in turn saves the power of polling channel in every 24 hours.

B.5   Client bootstrapping

B.5.1   Beacon

In one hour, there are N_{bcnprd} pre-specified beacon periods, each having $N_{bcnslot}$ of the same length. Every beacon slot has identical periodicity of p_{bcn}. For example, in Figure 5, each beacon period has $N_{bcnslot} = 2$ beacon slots with a periodicity of $p_{bcn} = 1hr$. A NB channel for downlink transmission is associated with each beacon slot. These NB beacon channels are distinctly picked from the TV channels registered for the gateway which increases robustness against noisy link and interference. The beacon slot structure along with channels are pre-specified and pre-loaded in the client radio. Here, the question arises what would happen if the WSDB in future ceases transmission on a particular beacon channel for the gateway? Although it is very infrequent, it needs to be addressed to comply with the regulation. In such a case, the gateway goes silent in the beacon slot associated with ceased channel. However, the clients continue to listen on that channel without violating the regulation. Finally, N_{bcnprd}, $N_{bcnslot}$, and p_{bcn} are adjusted based on application and expected traffic pattern. For example, for a deployment expecting high event-driven traffic, N_{bcnprd} is set to a higher value with lower p_{bcn}.

B.5.2   Join

On reboot, a client radio first locks the GPS and retrieves the current location and time with a precision of one second. It then hops across the beacon channels according to the previously specified beacon slot structure and listens for the beacon. Since the client is already time synced using GPS and knows beacon schedule, it requires minimal hopping depending on the channel quality. Each beacon frame embeds join slot information as MAC command in an encrypted LoRaWAN multicast frame. To be specific, each beacon frame contains the scheduling info of N_{jnslot} join slots between the

current and next beacon period. Hence, the info received in a beacon is only valid till the next beacon period. For example, in Figure 5, each beacon contains the scheduling info of following $N_{jnslot} = 3$ join slots. Here, the gateway books the join slots as an event-driven traffic. The benefit is twofold. First, N_{jnslot} can be adjusted depending on the expected join requests in a deployment over the time. Second, it utilizes no or low-utilized channels in that hour assigned for periodic assignments. It in turn impels variation in the channels used in the join slots with the time which increases robustness against noisy channels and long-term interference. Note that the uplink and downlink channels are same in the join slot.

Upon receiving the beacon, a client selects one of the join slots from the info embedded in the beacon. Since multiple clients may attempt to send join request at the same time, we need to ensure that clients are selecting join slots in a distributed manner to reduce the collision. Here, the client leverages dynamic quadratic hash function where the unique device id is used as the key. The gateway decides the coefficients of the hash function equation. To do so, it estimates the set of clients likely to send join request using set the difference between the provisioned clients for the deployment and clients already joined the network for periodic traffic. The coefficients chosen based on this estimated set are embedded in the beacon. For example, in Figure 5, $Client_0$ and $Client_1$ select two different join slots.

In the join slot, a client transmits the join request along with its location and slot requirement for the data communication. Upon receiving the join request, the gateway sends the client's location to the channel coordinator for the registration on the WSDB (see Figure 2). Once the registration of the client is done, the Whisper MAC manager gets the available channel for it and allocates the slots for data communication. The gateway then sends a join response incorporating the allocated slots and expiry of the associated channels.

Learning to Communicate Effectively Between Battery-free Devices

Kai Geissdoerfer
TU Dresden

Marco Zimmerling
TU Dresden

Abstract

Successful wireless communication requires that sender and receiver are operational at the same time. This requirement is difficult to satisfy in battery-free networks, where the energy harvested from ambient sources varies across time and space and is often too weak to continuously power the devices. We present Bonito, the first connection protocol for battery-free systems that enables reliable and efficient bi-directional communication between intermittently powered nodes. We collect and analyze real-world energy-harvesting traces from five diverse scenarios involving solar panels and piezoelectric harvesters, and find that the nodes' charging times approximately follow well-known distributions. Bonito learns a model of these distributions online and adapts the nodes' wake-up times so that sender and receiver are operational at the same time, enabling successful communication. Experiments with battery-free prototype nodes built from off-the-shelf hardware components demonstrate that our design improves the average throughput by 10–80× compared with the state of the art.

1 Introduction

The last few years have seen rapid innovation in battery-free systems [40], culminating in a number of real-world applications [1, 12, 27]. These systems pave the way toward a more sustainable Internet of Things (IoT) [7] by enabling small, cheap, and lightweight devices to perform complex tasks (e.g., DNN inference [20]) off ambient energy while using tiny, environmentally friendly capacitors as energy storage [40]. However, to replace today's trillions of battery-powered IoT nodes, battery-free devices must learn to communicate.

Challenge. The power that can be harvested from solar, vibrations, or radio signals is typically insufficient to continuously operate a device. A traditional energy-neutral device buffers harvested energy in a rechargeable battery and can *freely control* its average duty cycle to avoid power failures. Instead, a battery-free device cannot avoid power failures, and has *very limited control* over when the power failures begin and end. Fig. 1 illustrates this so-called *intermittent operation*. After executing for a short time, a battery-free device is *forced* to
Figure 1: Because ambient power is often weak, a battery-free node must buffer energy before it can wake up and operate for a short time period. This is known as intermittent operation.

become inactive and wait for a long, fluctuating time until its capacitor is sufficiently charged again. For example, when harvesting energy from indoor light, our prototype battery-free nodes need to stay off and recharge, on average, for hundreds of milliseconds before they can operate for at most 1 ms.

Many techniques have been developed to deal with intermittency on a *single* battery-free device [6, 11, 34], but how to communicate *between* intermittently powered devices is one of the most pressing problems yet to be solved [22, 28, 48]. This is due to the fact that device-to-device communication is a fundamental building block for a variety of network and system services, including optimal clock synchronization [26], ranging and localization [9, 21], sensor calibration [41], distribution and coordination of sensing and computing tasks [32], collaborative learning [47], and efficient and reliable wireless networking [25]. Realizing these services across battery-free devices has the potential to enable novel and more sustainable IoT and sensor network applications, from automatic contact tracing to planetary-scale environmental monitoring.

To be able to communicate, sender and receiver must be active and have enough energy for at least one complete packet transmission *at the same time*. However, since the nodes' activity phases are generally interleaved and short compared to their charging times, as visible from the real-world trace in Fig. 2a, it often takes thousands of wake-ups until two nodes encounter each other and communication becomes possible [19]. Moreover, after an encounter, the nodes quickly get out of sync if they become active immediately after a
(a) Because of their short and interleaved activity phases, battery-free devices often need a long time with hundreds of wake-ups until they encounter each other. Even after an initial encounter, the devices quickly get out of sync, rendering communication inefficient and unreliable.
(b) With Bonito, devices learn and exchange statistical models of their charging times and agree on a connection interval that ensures that both devices have sufficient energy at the same time. Maintaining a connection over multiple encounters enables efficient and timely communication.

Figure 2: The challenge of efficient battery-free device-to-device communication in (a) and our proposed protocol in (b).

recharge, as stipulated by the state of the art [8, 33] and apparent in Fig. 2a. This is because ambient energy varies across time and space [3], which leads to fluctuating and different charging times between the nodes.

Besides establishing a first encounter [19], active radio communication has been considered too demanding for battery-free devices [36]. Conversely, work on backscatter communication has focused on physical-layer issues, such as improving range and throughput, purposely considering high-energy environments, batteries, or cables to continuously power the devices in the experiments to avoid intermittency [29, 35, 38, 49]. However, when running off ambient energy, duty cycling of the backscatter transceivers becomes necessary [14, 29, 43]—and, without a battery, the intermittency problem occurs.

Contribution. This paper presents Bonito, the first connection protocol for battery-free wireless networks. Bonito provides reliable and efficient bi-directional communication despite the time-varying intermittency of battery-free devices.

The real-world trace in Fig. 2b illustrates the high-level protocol operation. Unlike the state of the art, Bonito enables two battery-free nodes, after an initial encounter, to maintain a *connection* across multiple consecutive encounters. To this end, Bonito continually adapts the *connection interval*, which is the time between the end of an encounter and the beginning of the next encounter. A shorter connection interval provides more communication opportunities in the long run. However, a connection interval that is shorter than any of the nodes' charging times breaks the connection and requires the nodes to wait for a long time until they encounter each other again. Thus, the challenge is to keep the connection interval as short as possible without losing the connection, which is difficult in the face of time-varying charging times.

One of our key insights is that, depending on the scenario and energy-harvesting modality, the charging time of a battery-free node approximately follows well-known probability distributions. We leverage this insight in Bonito by letting each node *continuously learn and track* the parameters of a model that approximates the distribution of locally observed charging times against non-stationary effects (e.g., changes in mean or variance). Then, to maintain an efficient and reliable connection, the nodes exchange at every encounter their current model parameters and jointly adapt the connection interval.

We implement Bonito on a custom-designed ultra low-power battery-free node. Our prototype is built from off-the-shelf components, including an ARM Cortex-M4 microcontroller that features a 2.4 GHz Bluetooth Low Energy (BLE) radio. The node harvests energy from a solar panel or a piezoelectric harvester, using a 47 µF capacitor as energy storage.

To evaluate Bonito through testbed experiments and fairly compare it against two baselines, we use up to 6 Shepherd ob-
Figure 3: The top plot shows an example trace of real kinetic harvesting power during jogging (see picture in Fig. 4a). The middle and bottom plots show the corresponding energy stored in the capacitor and the resulting charging times of a simulated battery-free device.

Figure 4: Pictures from two of the five scenarios in which we use synchronized Shepherd nodes [18] to record energy-harvesting traces.

servers [18] to record and replay real-world energy-harvesting traces from 5 diverse scenarios. Our results show, for example, that Bonito maintains connections for hundreds of consecutive encounters, and that it outperforms the state of the art by 10–80× in terms of throughput. We also conduct a case study that demonstrates the utility of Bonito for accurate and timely occupancy monitoring in homes and commercial buildings.

Overall, this paper contributes the following:

- We collect 32 h of energy-harvesting traces from 5 different scenarios. Our analysis of these traces provides new insights into spatio-temporal intermittency patterns.
- We design the Bonito protocol. Bonito enables, for the first time, reliable and efficient communication between intermittently powered battery-free devices.
- We demonstrate an efficient implementation of Bonito on a prototype node with a 3.1 mm³ ceramic capacitor.
- Results from testbed experiments and an occupancy monitoring case study provide evidence that Bonito performs well under a diverse range of real-world conditions.

2 Motivation

While previous work on intermittency has focused on individual battery-free devices [6,11,33] or discovery of neighboring devices [19], reliable and efficient device-to-device communication is still an open challenge. By *device-to-device communication* we mean the regular exchange of application data between two battery-free devices after they have successfully discovered each other through a first encounter [19].

To motivate the need for our work, we consider the scenario of battery-free wearables. Fig. 3 shows real-world data from a piezoelectric energy harvester that is attached to the ankle of a person (see Fig. 4a). The upper plot shows the harvest-

ing power while the person is jogging, recorded by a Shepherd node. Shepherd is a measurement tool that records time-synchronized voltage and current traces from one or more energy-harvesting nodes with high rate and resolution [18]. The power spikes correspond to when the foot strikes the ground, with significantly lower harvesting power during the rest of the stride cycle. Based on trace-driven simulations, the middle plot shows the corresponding amount of harvested energy stored in an ideal 17 µF capacitor powering a battery-free device that turns on when the capacitor voltage exceeds 3 V and turns off when the capacitor voltage falls below 2 V. We see that when the device powers up, the stored energy is quickly consumed, forcing it to turn off already after about 1 ms. While powered off the harvesting power exceeds the standby power, so energy is accumulated and the capacitor voltage rises again. Compared to the short activity phases, the time needed to charge the capacitor, shown in the bottom plot of Fig. 3, is much longer and varies significantly over time.
The variability of a node's charging time is a function of its location and the associated energy environment, that is, how much power the harvester delivers at any given time. Thus, two battery-free devices, even when they are physically close to each other, have a different energy environment and therefore experience different charging times.

As an example, Fig. 5 plots the charging times of two devices during jogging over one hour. One device is powered by a piezoelectric harvester attached to the left ankle of a person, while the other device is powered by the same type of harvester attached to the right ankle of the person (see Fig. 4a). Each point in Fig. 5 indicates the charging times of both de-

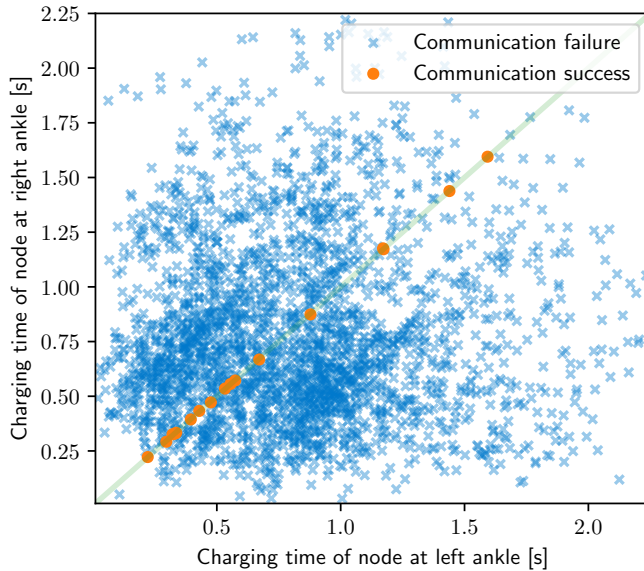
Table 1: Overview of energy-harvesting datasets we record in a variety of scenarios.


Figure 5: Charging times of two battery-free devices powered by kinetic harvesters attached to a jogger's ankles (see Fig. 4a). Using the greedy approach, the devices communicate successfully only in 0.04 % of the cases in which the charging times are almost identical.

Figure 6: Success rate of greedy approach in trace-driven simulations, averaged across all pairs of devices (i.e., links) in a given dataset.

vices when they begin to charge their $17\,\mu F$ capacitors at the same time from the same initial charge. We observe that in many instances the two nodes have vastly different charging times. This means that if nodes become active as soon as they reach the turn-on threshold, which is the state-of-the-art approach, called *greedy* and illustrated in Fig. 2a, the nodes often wake up with an offset that prevents communication, despite a successful encounter at the previous wake-up. Indeed, the success rate for the two nodes in Fig. 5 is less than 0.04 %. This leads to poor communication reliability and efficiency as the nodes more often than not fail to exchange their data.

To assess the generality of these observations, we record distributed energy-harvesting traces in diverse scenarios using multiple Shepherd nodes [18]. Table 1 lists the main characteristics of the five datasets we collected:

- The full *jogging* dataset comprises traces from two participants, each equipped with two piezoelectric harvester at the ankles and a solar panel at the left wrist (see Fig. 4a). The two participants run together for an hour in a public

park, including short walking and standing breaks.
- For the *stairs* dataset, we recorded traces from six solar panels that are embedded into the surface of an outdoor stair in front of a lecture hall. Over the course of one hour, numerous students pass the stairs, leading to temporary shadowing effects on some or all of the solar panels.
- The *office* dataset comprises traces from five solar panels mounted on the doorframe and walls of an office with fluorescent lights. During the one-hour recording, people enter and leave the office and operate the lights.
- The *cars* dataset contains traces from two cars. Each car is equipped with three piezoelectric harvesters mounted on the windshield, the dashboard, and in the trunk. The cars drive for two hours in convoy over a variety of roads.
- The *washer* dataset includes five traces from piezoelectric harvesters mounted on a WPB4700H industrial washing machine, as shown in Fig. 4b, while the machine runs a washing program with maximum load for 45 min.

Fig. 6 plots for each dataset the average success rate across all pairs of devices (i.e., communication links) in the scenario. Even in the most favorable scenario, *stairs*, where the solar panels receive a fairly constant and similar energy input from natural sunlight, we find that the greedy approach succeeds in only 16 % of the cases. In all other scenarios, the success rate ranges below 3.5 %. Our experiments on real battery-free nodes in Sec. 5 confirm these trace-driven simulation results.

3 The Bonito Protocol

This section describes the Bonito protocol. The Bonito protocol enables two battery-free devices to stay connected after a first encounter, which can happen either coincidentally or with the support of a neighbor discovery protocol [19].

3.1 Overview

Bonito aims to make nodes repeatedly encounter each other so they can exchange application data reliably and efficiently, as shown in Fig. 2b. To ensure that nodes wake-up with a time offset small enough for a successful encounter, they agree at every encounter on a new *connection interval* T_C. This is the time between the end of the current encounter and the beginning of the next (i.e., planned) encounter.

Main idea and approach. For two nodes i and j with known charging times c_i and c_j, the shortest possible connection interval T_C^* is simply the maximum of their charging times

$$T_C^* = max(c_i, c_j) \tag{1}$$

If a shorter connection interval $T_C < T_C^*$ is used, then one node does not reach the required energy level to become active by T_C. Thus, the encounter fails, preventing the nodes from agreeing on the next connection interval—the connection is *lost*. A lost connection entails that the nodes often need to wait for a long time until they encounter each other again to resume communication. However, choosing a longer connection interval $T_C > T_C^*$ to mitigate the risk of a lost connection adds unnecessary delay as nodes, after having reached the required energy level, are forced to wait before they wake up at T_C.

The key challenge is to determine the connection interval T_C such that both nodes have enough energy while introducing only minimal delay. This is difficult as the charging times c_i and c_j are unknown and time-varying, as discussed in Sec. 2.

Using a probabilistic approach, we address this problem as follows. Let p be the probability that nodes i and j have sufficient energy to become active after a connection interval T_C. This corresponds to the probability that the nodes' charging times, c_i and c_j, are shorter than the connection interval T_C. Modeling c_i and c_j as random variables with a strictly monotonically increasing joint cumulative distribution function (cdf) $F_{i,j}$, this translates into

$$p = F_{i,j}(c_i = T_C, c_j = T_C) \tag{2}$$

Solving for T_C yields the minimum connection interval that guarantees, with a user-defined probability p, a successful encounter of the two nodes at their next wake-up

$$T_C = F_{i,j}^{-1}(p) \tag{3}$$

where $F_{i,j}^{-1}$ is the inverse joint cdf of c_i and c_j.

Base protocol. In practice, the joint cdf $F_{i,j}$ is rarely known a priori. Moreover, $F_{i,j}$ can only be estimated online by the nodes based on full knowledge of each other's charging times.

Unfortunately, this requires frequent communication between battery-free nodes—precisely what Bonito intends to enable.

To circumvent this chicken-and-egg problem, we assume that the charging times, c_i and c_j, are statistically independent. In this case, the joint cdf $F_{i,j}$ is the product of the marginal cdfs F_i and F_j. The marginal cdfs can be estimated locally by each node from observations of their own charging times.

Based on these insights, we propose the following main steps of the Bonito protocol:

1. Each node i continuously estimates the marginal cdf F_i of its charging time based on local measurements.
2. When two nodes i and j encounter each other, they exchange their current estimates of F_i and F_j.
3. Using the same inputs (i.e., the marginal cdfs F_i and F_j and the user-defined probability p), both nodes compute the same new connection interval T_C according to (3).
4. Both nodes become active and communicate after the new connection interval T_C, and continue with step 2.

In this way, Bonito adapts the connection interval to changes in the energy environment, effectively enabling battery-free nodes to stay connected across several hundreds of subsequent encounters, as demonstrated by our experiments in Sec. 5.

To achieve this performance, we first need to answer the following key questions in our design of Bonito:

- How to compactly represent and exchange the marginal cdfs F_i and F_j in the face of limited energy (Sec. 3.2)?
- How to learn and track online an accurate estimate of F_i against a changing energy environment? (Sec. 3.3)
- How to efficiently compute the inverse joint cdf $F_{i,j}^{-1}(p)$ to obtain the connection interval T_C? (Sec. 3.4)

3.2 Modeling Charging Time Distributions

Because of the small energy storage, battery-free devices can only exchange a limited amount of data during an encounter. Thus, the marginal cdfs F_i and F_j must be represented in a compact form in order to be able to exchange them.

Unlike the common belief that the duration of a recharge is completely random [11, 31], we make the empirical observation that, in the scenarios we considered, the nodes' charging times can be faithfully modeled by well-known distributions. The rightmost column of Table 1 lists the models we use for each dataset. To illustrate, Fig. 7 plots representative charging time distributions and the corresponding models for the stairs, cars, and office datasets. Non-stationary effects like a time-varying mean are removed in the plots as these are effectively handled by our online learning approach detailed in Sec. 3.3.

We observe in Fig. 7a that when harvesting energy from outdoor solar with a constant harvesting voltage, the charging time can be modeled by a normally distributed random variable. The intuition is that temporary environmental effects, such as shadowing and change in incidence angle, let the charging time vary around a certain value. Fig. 7b shows that an exponential distribution is often a good fit when harvesting kinetic energy. This can be explained by the decaying
(a) Stairs dataset, normal distribution.   (b) Cars dataset, exponential distribution.   (c) Office dataset, Gaussian mixture model.

Figure 7: Charging time distributions of individual nodes. The nodes' charging times can be modeled by well-known distributions.

response of a piezoelectric harvester to the distinct impulses of a car during driving (e.g., acceleration, breaking, bumps) or a person during jogging (see Fig. 3). In the washer scenario, instead, we find that the continuous shaking of the industrial washing machine over long periods induces approximately normally distributed charging times. Looking at Fig. 7c, we see that in the office scenario the charging times are mostly distributed around a certain value. However, the maximum power point tracking (MPPT) of the DC-DC converter used in this scenario, which periodically disconnects the charger for a short time, leads to a second peak. We approximate this distribution with a Gaussian mixture model (GMM).

These observations motivate us to model the marginal cdf F_i of a node's charging time in the scenarios we considered through the parameters of a normal distribution (2 parameters), an exponential distribution (1 parameter), or a GMM (6 parameters for two Gaussians and two weights). The last column of Table 1 lists the corresponding model for each of the datasets. The jogging dataset contains traces from different types of harvesters: We use an exponential distribution to model the charging times of kinetic harvesting nodes and a normal distribution for the solar harvesting nodes. During an encounter, a node only needs to share the type of model and the current estimates of the model parameters.

3.3 Learning Distribution Parameters Online

We now turn to the problem of estimating the parameters of a given charging time distribution based on local observations. Given a sample of n independent and identically distributed observations, the log-likelihood $\mathcal{L}(\theta \mid x)$ and the corresponding maximum likelihood estimator $\widehat{\theta}$ are given by

$$\mathcal{L}(\theta \mid x) = \ln\left(\prod_{i=1}^{n} f_\theta(x_i)\right) = \sum_{i=1}^{n} \ln f_\theta(x_i) \qquad (4)$$

$$\widehat{\theta} = \arg\max_{\theta} \mathcal{L}(\theta \mid x) \qquad (5)$$

where $f_\theta(x_i)$ is the conditional probability to observe x_i if the underlying distribution is parameterized with θ.

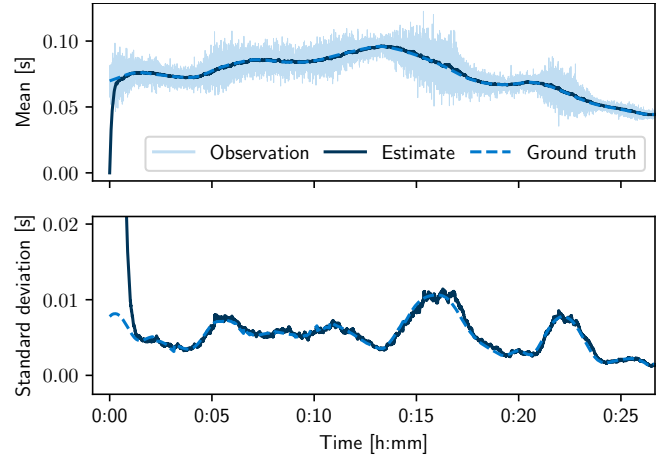
Unfortunately, vanilla maximum likelihood estimation is not viable in our setting. First, the observations of the charg-


Figure 8: Varying mean and standard deviation over a moving window of one of the trace from the stairs dataset reveal non-stationarity. Using SGD, the changing distribution parameters are tracked online.

ing time become available only one by one at runtime, yet the nodes do not have enough memory and energy to recompute the estimator with every new observation. Further, the charging time distributions are non-stationary. For instance, the dashed lines in Fig. 8 reveal trends in the mean and standard deviation of a node's charging time from the stairs dataset. Thus, an approach is needed that dynamically adjusts the parameter estimates to changing energy harvesting conditions.

To address these problems, Bonito learns the distribution parameters online using stochastic gradient descent (SGD), which has become a popular method for training a wide range of machine learning models [5]. Compared to a sliding window based approach, SGD is less computationally demanding as the parameter update is only computed for the current observation rather than for a set of past observations that also have to be kept in memory. If the gradient of $\mathcal{L}(\theta \mid x)$ is known, one solution to (5) is to iteratively adjust $\widehat{\theta}$ along the gradient, known as gradient descent

$$\nabla \mathcal{L}(\theta \mid x) = \nabla \sum_{i=1}^{n} \ln f_\theta(x_i) \qquad (6)$$

$$\widehat{\theta} = \widehat{\theta} + \eta \cdot \nabla \mathcal{L}(\widehat{\theta} \mid x) \qquad (7)$$

By pulling the ∇ operator in (6) into the sum, the update step in (7) can be split into a series of updates for every individual observation x_i. This yields the update equation of SGD

$$\widehat{\theta}_i = \widehat{\theta}_{i-1} + \eta \cdot \nabla \mathcal{L}(\widehat{\theta} \mid x_i) \qquad (8)$$

Sec. A derives the gradient equations required to solve (8) for the normal, exponential, and Gaussian mixture models. By keeping the learning rate η constant, Bonito implicitly reduces the weight of old observations relative to more recent observations. This way, devices dynamically learn changing properties of the charging time distribution locally, without information exchange with other devices.

Example. Fig. 8 illustrates how Bonito learns and tracks mean and standard deviation of a non-stationary normal distribution. To obtain ground truth, we sample charging times (i.e., observations) from a known normal distribution, whose mean and variance change dynamically over time. We extract these changes from one of the traces in the stairs dataset using a 2 min moving average filter. We can see in Fig. 8 that the parameter estimates of Bonito converge from their initial values (zero mean and unit standard deviation) to the true ground truth parameters within less than a minute. Then the estimates closely follow the changes of the underlying distribution.

3.4 Computing Inverse Joint CDF Efficiently

Having shared the type of model and the current estimates of the model parameters during an encounter, Bonito needs to compute the new connection interval T_C from the inverse joint cdf $F_{i,j}^{-1}$ for a user-defined probability p. This is difficult since there exists no closed-form solution for most bivariate distributions, let alone for joint cdfs of different distribution families (e.g., when a solar and a kinetic energy harvesting node in the jogging scenario want to communicate). Instead, we have to solve (3) numerically, while taking into account the energy and compute constraints of battery-free devices.

We are interested in the connection interval T_C where the joint cdf is equal to the user-defined target probability, that is, $F_{i,j}(T_C) = p$. This yields the following objective function

$$f(T_C) = F_{i,j}(T_C) - p = F_i(T_C) \cdot F_j(T_C) - p = 0 \qquad (9)$$

Note that $f(T_C)$ has a single root—the sought solution—as $F_{i,j}$ is strictly monotonically increasing. Bonito solves this problem using the well-known bisection method, which iteratively finds the root of any continuous function that has its root inside a bracket (i.e., search interval). Indeed, we can derive such a bracket based on the inverse cdfs of our marginal distributions, which either have a closed form solution (exponential and normal) or are easy to approximate (GMM).

To derive a lower bracket, we first note that $F(x) < 1$ for any cdf F. It follows that $F_{i,j}(x=z, y=z) = F_i(x=z) \cdot F_j(y=z) < \min(F_i(x=z), F_j(y=z))$ and therefore the lower bracket

$$F_{i,j}^{-1}(p) > \max\left(F_i^{-1}(p), F_j^{-1}(p) \right) \qquad (10)$$
Figure 9: Bracketing the inverse joint cdf based on the inverse cdf of the marginal distributions enables efficient computation of the connection interval on resource-constrained battery-free devices.

To derive an upper bracket, we introduce $q = \sqrt{p}$ and $c = \max(F_i^{-1}(q), F_j^{-1}(q))$. Let F_m be the marginal cdf (i.e., either F_i or F_j) such that $F_m^{-1}(q) = c$, that is, the marginal cdf that reaches q *later*. Let F_n be the other marginal cdf that reaches q *sooner*. From $F_n(c) \geq F_m(c)$ follows $F_{i,j}(c) = F_m(c) \cdot F_n(c) \geq F_m(c) \cdot F_m(c) = q^2 = p$. Finally, because $F_{i,j}(c)$ is monotonically increasing, we obtain the upper bracket

$$F_{i,j}^{-1}(p) \leq \max(F_i^{-1}(q), F_j^{-1}(q)) \qquad (11)$$

Example. Fig. 9 shows an example, where (10) and (11) are used to determine an initial bracket for $F_{i,j}^{-1}(p = 0.75)$. The resulting bracket $[0.61, 0.77]$ is already relatively tight, and therefore we find the solution $F_{i,j}^{-1}(p = 0.75) = 0.88$ with a tolerance of 0.01 after only three bisection steps.

3.5 Impact of Target Probability

The target probability p is a key parameter of the Bonito protocol that must be set by the user. It specifies the probability that both devices have accumulated enough energy in their capacitors to become active after a connection interval T_C. A high target probability requires a long connection interval T_C, increasing communication delay and lowering throughput.

To illustrate how the choice of p impacts communication reliability and efficiency, we run trace-driven simulations as detailed in Sec. 2 on the traces from the datasets in Table 1. We use two metrics to quantify the performance of Bonito: As a proxy for communication reliability, we define the *success rate* as the ratio of successful encounters with Bonito to the total number of wake-ups. As a proxy for communication efficiency, we consider the *relative delay* as the median of all successful connection intervals with Bonito divided by the median of the optimal clairvoyant solutions according to (1).

Fig. 10 plots for each dataset success rate and relative delay averaged across all links. We can observe the following:

- A higher target probability p leads to a higher success rate, which demonstrates the plausibility of our approach.
Figure 10: Trace-driven simulations reveal that the rate of successfully arranged encounters matches the user-defined target probability. The price to pay in terms of latency depends on the model of the underlying charging time distribution.

In most cases, the success rate is even slightly higher than requested, presumably due to small model errors.

- Since connection losses are costly, a higher target probability is preferable in practice. Fig. 10 shows that the price to pay in terms of a higher relative delay depends on the scenario. For the cars and jogging datasets, where most or all links include at least one node with approximately exponentially distributed charging times, the relative delay increases exponentially with p, due to the heavy tail of the distribution. For GMM (office), the increase is moderate, whereas it is hardly noticeable for the normal distribution (washer and stairs).

4 Implementation

In this section, we describe the hardware and software components of our prototype implementation.

4.1 Hardware

We design a ulta low-power battery-free node based on the popular Nordic Semiconductor nRF52805 microcontroller (MCU). This particular MCU features a 2.4 GHz BLE radio and a state-of-the-art 32-bit 64 MHz ARM Cortex-M4, which is powerful enough to complete also more demanding computations in a short time, benefitting overall system efficiency. To enable low-power timekeeping between wake-ups, the MCU is equipped with a 32 kHz crystal with ± 20 ppm frequency tolerance. A TI BQ25504 DC-DC step-up converter charges a 2 mm × 1.25 mm × 1.25 mm 47 µF multilayer ceramic capacitor (MLCC) from a connected solar panel or a piezoelectric energy harvester. Once the capacitor voltage reaches a hardware-programmable threshold of 3.3 V, the BQ25504 sets one of its pins high. This pin is wired to a TI TS5A23166 analog switch that connects the MCU to the capacitor-buffered supply voltage.

Due to its DC bias characteristics, the capacitor has an ef-
Figure 11: Prototype battery-free node based on the nRF52805 MCU. A sustainable 3.1 mm^3 ceramic capacitor is used as energy storage.
Figure 12: Packet format. Using Bonito, nodes exchange between 5 B and 25 B carrying model type and parameters during an encounter.

fective capacitance of only 17 µF at 3.3 V. This allows for a maximum active time of around 1 ms per wake-up. A larger capacitance would increase the active time per wake-up and the charging time between wake-ups. To minimize the physical dimensions and the price of the node, we choose the minimum capacitance that allows the nodes to remain active for long enough to compensate for clock drift accumulated over a connection interval of 5 s (see Sec. 4.2).

The node also integrates a circuit to measure the current flow from the harvester, which can be used as a sensing signal [39]. The two-layer printed circuit board (PCB) shown in Fig. 11 measures 20 mm × 20 mm. The total cost of all components is $8.73.

4.2 Software

We implement Bonito and the Find neighbor discovery protocol [19] on our battery-free nodes. Find is used to establish an initial encounter after a connection loss or a power failure.

Bonito protocol settings. We use the 2 Mbit/s BLE mode and the frame structure depicted in Fig. 12. Depending on the model type, encoded by one byte, a packet carries 1, 2, or 6 model parameters represented by 32-bit floating point values.

To jointly agree on the next connection interval, Bonito requires nodes to exchange messages bi-directionally during an encounter. The exact sequence of packet exchanges is subject to application requirements and can be flexibly configured. We implement the packet sequence shown in Fig. 13. When two nodes encounter each other using Find, one of the nodes receives the first beacon and replies with an acknowledgement. At all following encounters, the node that received the first beacon starts to listen at the time agreed on using Bonito.
Figure 13: After the initial encounter, nodes use Bonito to agree on a connection interval. At the next encounter, one of the nodes starts to listen and the other node transmits its packet after a grace period to account for clock drift due to the long charging times. After receiving this packet, the listening nodes replies with its own packet.

Due to the small energy buffer, a node can keep the radio on for at most $T_{wdw} = 1$ ms. Thus, the maximum listening time is $T_{l,max} = T_{wdw} - T_{tx} - T_{ta} = 820\,\mu s$, where $T_{ta} \approx 40\,\mu s$ is the time it takes to switch from receive to transmit mode and $T_{tx} = 140\,\mu s$ is the airtime of a packet with 6 model parameters and 4 B of application data. To increase the robustness to clock drift in the face of long charging times and hence long connection intervals, we let the node that sends first transmit its packet after a grace period of $T_g = 0.5 \cdot T_{l,max} - 1.5 \cdot T_{tx} = 200\,\mu s$. We can thus tolerate an offset of up to $\pm 200\,\mu s$ between the clocks of the two nodes, which corresponds to a maximum connection interval of 5 s when taking into account the frequency tolerance of the 32 kHz crystal oscillator. Upon receiving the packet, the other node switches to transmit mode and sends its own packet.

In our current implementation of Bonito, the devices consider a connection as lost whenever a planned packet exchange fails, for example, due to fading, external interference, or when one of the two devices does not reach the turn-on threshold by the end of the connection interval. In this case, they return to discovery mode and use Find to re-establish the connection.

Runtime support. In addition to Bonito and Find, we implement an efficient *soft intermittency* runtime, where the MCU is gracefully suspended to an ultra low-power mode before an impeding power failure [19]. This reduces the costs associated with a cold start after a hardware reset and allows to keep track of time between consecutive wake-up events using the built-in real-time clock (RTC). To this end, a node periodically samples the capacitor voltage during charging with the built-in analog-to-digital converter (ADC) until the capacitor voltage reaches a software-defined turn-on threshold. Then the node executes protocol and application code until it is interrupted by the power-fail comparator, upon which it immediately transitions back into low-power mode to replenish its energy buffer.

Although our runtime tries to prevent hardware resets, after multiple seconds without any energy input, the sleep current drains the remaining charge from the capacitor and the node eventually powers off. While powered off, the on-board static random access memory (SRAM) is subject to decay, that is, bits that were set to one may flip and become zero after some time. To still retain the trained model of a node's charging time distribution across short power failures, we store it in a dedicated section of the SRAM. After every model update, we compute a checksum over this section and store it next to the model parameters. If the recomputed checksum after a hardware reset does not match the checksum stored in memory, we conclude that the memory is corrupted and restart training the model with the initial parameters.

5 Evaluation

This section uses testbed experiments to evaluate Bonito on real battery-free nodes under realistic, repeatable conditions. We start by showing in Sec. 5.2 how Bonito dynamically adjusts the connection interval to changes in the nodes' charging times to maintain long-running connections. In Sec. 5.3, we compare Bonito against two baseline approaches. Finally, in Sec. 5.4, we quantify the runtime overhead of Bonito. Our experiments reveal the following key findings:

- Bonito establishes connections that outlast on average hundreds of consecutive encounters even between nodes that harvest from different types of energy sources.
- Bonito improves the throughput by 10–80× compared with the current state of the art. It achieves this by consciously keeping the connection interval as short as possible while maintaining a high success rate that agrees to within 1 % of the requested target probability.
- Depending on the distribution model, Bonito consumes between 4 % and 25 % of the energy available per wake-up on our nodes. The energy cost of losing a connection is 1000× higher than the energy overhead of Bonito.

5.1 Testbed and Settings

We connect two battery-free nodes (see Fig. 11) to two Shepherd observers [18]. In addition to recording spatio-temporal harvesting traces (see Sec. 2), Shepherd can also replay previously recorded traces and monitor the behavior of connected battery-free devices. The observers synchronously replay for all 60 links in our datasets (see Table 1) the two corresponding energy-harvesting traces. At the same time, the observers log the serial output and GPIO events of the attached nodes, which we use to compute performance metrics. In total, we collect measurements from 218 hours of testbed experiments.

For the stairs, office, and washer scenarios, we replay the recorded energy-harvesting traces as is. When using the original traces from the cars and jogging scenarios, however, we were not able to collect sufficient data points. The reason is that the piezoelectric harvesters were selected and tuned for the frequency and amplitude of the washer scenario, which led to a relatively low harvesting power in the cars and jogging scenarios, as evident from the small number of wake-ups in Table 1. Because it can take thousands of wake-ups until two nodes encounter each other, we had to scale the cars and jogging traces by a factor of five to allow for a meaningful
Figure 14: Real-world trace from testbed experiments showing the charging times of two nodes from the cars dataset. By dynamically adjusting the connection interval, Bonito maintains a connection for 37 min until the cars leave the highway and enter stop-and-go traffic; the charging times increase dramatically and the connection breaks.

evaluation. Note that this does not change the dynamics and shape of the charging time distributions, nor does it affect relative performance when comparing different approaches.

In all experiments, we configure Bonito with a target probability of $p = 0.99$. We use a learning rate of $\eta = 0.01$ for the normal and exponential models and $\eta = 0.001$ for GMM, which we found to perform well in a wide range of scenarios.

5.2 Maintaining Long-running Connections

We begin by looking at how well Bonito can maintain a connection between battery-free devices. As an illustrative example, Fig. 14 shows the charging times of two nodes from the cars dataset and the connection interval determined by Bonito over the course of 55 min. Bonito successfully maintains the connection for more than half an hour by dynamically adjusting the connection interval based on the continuously updated models of the nodes' charging time distributions. Then, after around 37 min, the two cars driving in convoy exit the highway and enter stop-and-go traffic. As a result, the charging times increase suddenly and exceed the connection interval—the connection is lost. At this point, the nodes switch over to executing the Find neighbor discovery protocol and successfully reconnect after roughly 10 min. Afterward, Bonito takes over and again maintains a connection for several minutes.

Fig. 15a plots for all datasets the cdf of the connection duration in terms of the number of encounters, while Fig. 15b plots it in terms of time for the unscaled datasets (see Sec. 5.1). Overall, we find that in 90 % of the cases, the nodes stay connected for at least 30 consecutive encounters, and 40 % of the connections last for 800 encounters or more. This demonstrates that Bonito enables, for the first time, reliable and efficient communication between intermittently powered nodes.

5.3 Bonito versus Baseline Approaches

We now compare Bonito against two baseline approaches:

- Greedy: This is the current state of the art. Using Greedy, nodes wake up and attempt to communicate as soon as
(a) cdf of connection duration in terms of number of encounters.
(b) cdf of connection duration in terms of time.

Figure 15: Bonito maintains connections over hundreds of encounters even in challenging scenarios with different types of energy sources.

they reach the minimum required energy level. Greedy is the prevalent execution model in the intermittent computing literature [8,33] as it maximizes the effective duty cycle of a battery-free device.

- Modest: As a complementary approach to Greedy, we design Modest. Using Modest, each node keeps track of the maximum observed charging time c_{max}. During an encounter, two nodes i and j share their current maximum charging times $c_{max,i}$ and $c_{max,j}$, and agree to meet again after a connection interval of $T_C = \max(c_{max,i}, c_{max,j})$.

Our comparison uses two end-to-end metrics that also account for periods where Find runs to establish a first encounter after a connection loss or power failure. *Throughput* is the number of packets delivered from one node to another node per time unit. Note that traffic is always bi-directional, that is, the same number of packets is also delivered in the other direction (see Fig. 13). *Latency* is the time between two consecutive packet exchanges. We also consider *success rate*, which is the ratio of successfully arranged encounters to the total number of trials when using Greedy, Modest, or Bonito.

Fig. 16 plots for each dataset the throughput gains of Bonito and Modest over Greedy. We see that Bonito improves the throughput by 10–80×. For example, for the stairs dataset, Bonito achieves a throughput of 15.18 pkt/s versus 0.33 pkt/s with Greedy. Modest outperforms Greedy across the board, too, but often falls far short of Bonito's throughput.

To understand the reasons for the significant performance differences among the different approaches, we plot in Fig. 17 success rate and latency for the stairs dataset. As the charging
Figure 16: Throughput improvement over Greedy. By maintaining connections over many wake-ups, the average number of encounters with Bonito is at least an order of magnitude higher than with Greedy.

(a) Success rate   (b) Latency

Figure 17: Detailed comparison of performance metrics for the stairs scenario. Bonito achieves a high success rate that is on a par with the Modest approach, while providing a significantly lower latency.

times vary across time and space, Greedy achieves a low success rate of only 11.48 % (see Fig. 17a). This means that in 9 out of 10 cases the nodes loses the connection right after the first encounter. Every time the connection is lost, the nodes cannot communicate until they reconnect, causing excessively long latencies as visible in Fig. 17b. Instead, Modest chooses the connection interval highly conservatively, which leads to a high success rate of 99.92 % but also long latencies. Bonito provides much shorter latencies at almost the same high success rate, which agrees to within 1 % of the requested target probability. By aiming to keep the connection interval short and to avoid the latency associated with reconnecting after a connection loss, Bonito significantly increases the end-to-end throughput compared with the two baseline approaches.

5.4 Bonito's Runtime Overhead

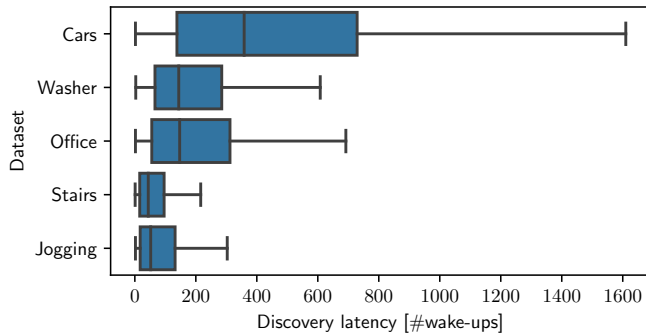
Next, we evaluate the runtime overhead of Bonito based on the logs from the testbed experiments. The overhead can be broken down into three components: (*i*) updating the model parameters using SGD, (*ii*) exchange of the model parameters over wireless during an encounter, and (*iii*) computing the inverse joint cdf to obtain the connection interval.

The time required to update the model is constant: 1.3 μs for exponential, 3.2 μs for normal, and 28.8 μs for GMM. This constitutes up to 2.8 % of the around 1 ms active time per wake-up. Similarly, the airtime to exchange 4, 8, or 24 bytes
Figure 18: Distribution of execution times on our battery-free node when computing the inverse joint cdf. The execution time depends on the number of model parameters and varies with the number of bisection steps needed to satisfy the required tolerance.
Figure 19: The energy overhead of Bonito ranges between 4 % and 25 % of the energy available per wake-up on our nodes. In absolute terms, the cost to recover from a lost connection is 1000× higher.

of model parameters is fixed and determined by the bitrate of the BLE radio. By contrast, Fig. 18 shows that the time to compute the inverse joint cdf varies depending on the number of bisection steps required to reach the desired tolerance.

In terms of energy, our battery-free nodes have an energy budget of 27.5 μJ per wake-up. Fig. 19 shows for each model the median percentage of energy budget spent by Bonito. We can see that the required energy mainly depends on the number of model parameters and the computational complexity of evaluating the inverse joint cdf. In the worst case, for GMM, Bonito consumes 7.1 μJ, which amounts to about 25 % of the available energy per wake-up. To set this into perspective, Fig. 20a plots for all datasets the time it takes for two nodes to synchronize with the Find neighbor discovery protocol [19] in terms of the number of wake-ups, while Fig. 20b plots it in terms of time for the unscaled datasets (see Sec. 5.1). On average it takes 283 wake-ups, or 7782.5 μJ, to synchronize after a lost connection—1000× more than the energy required by Bonito to maintain a connection. This demonstrates that, overall, the absolute energy costs of Bonito are well spent.

6 Case Study: Occupancy Monitoring

Occupancy monitoring is essential to save energy in homes and commercial buildings [10, 16]. Recently, it has also become an important tool to manage the spread of infectious diseases, such as SARS-CoV2 [37]. To assess the potential of Bonito for real-world battery-free applications, we conduct an


(a) Discovery latency in terms of number of wake-ups.

(b) Discovery latency in terms of time.

Figure 20: Synchronizing two devices with the Find neighbor discovery protocol takes a long time and consumes significant energy. Using Bonito, devices can establish long-running connections to periodically exchange data without the need to resynchronize.

occupancy monitoring case study with our prototype nodes.

Occupancy sensor. To efficiently count the number of people in a room, we use the solar panel as a sensor [23, 39] to detect when a person enters or leaves the room. Fig. 21 shows the solar panel current of two nodes mounted next to each other on a doorframe (see Fig. 22), when a person enters the room in Fig. 21a and when a person leaves the room in Fig. 21b. To detect the direction of movement, the nodes record the time when they detect the onset of the shadowing by the person. Then the nodes exchange the recorded times and compute the time difference τ. The sign of τ indicates the direction.

Setup. We mount two battery-free nodes equipped with IXYS SM141K06L solar panels next to each other on the doorframe at the entrance of an office room, as shown in Fig. 22. The nodes sample the solar panel current with a sampling rate of 1 kHz, and record the time when the solar panel current falls below 87.5 % of its average value. The nodes run Bonito and insert the timestamp of detected events into the packets. Together with logging information (charging time, connection interval, etc.) every packet carries 26 B of application data.

Because the clocks of the two nodes are not synchronized, timestamps are transmitted relative to the start of the corresponding packet. To this end, nodes measure the time between the detected event and the start of the transmission and insert the result into the packet. The receiving node timestamps the reception of the packet and converts the contained relative timestamp to its local clock. Finally, by relating a received
(a) Person entering the room: $\tau > 0$
(b) Person leaving the room: $\tau < 0$

Figure 21: The shadow of a person passing ambient light harvesting devices on a doorframe causes a distinct temporal pattern in the solar panel current. By comparing the times of the onset of the shadowing on the two nodes, we can determine the direction of movement.

timestamp to the timestamp of the corresponding event that was recorded locally, the nodes compute the time difference τ.

The nodes transmit the result over wireless to an nRF52840 development board that serves as a base station. We configure the base station to timestamp the reception of packets containing a detected event and button presses of two on-board push buttons, one for each direction. Four participants randomly enter and leave the room one by one. Another person records ground truth by pressing the corresponding button on the nRF52840 board precisely when a person passes through the doorframe.

Results. The confusion matrix in Table 2 shows that the system correctly classified 60 out of 61 events, corresponding to an accuracy of 96 %. It missed just one in-event, and falsely reported an in-event and an out-event for a single in-event.

Fig. 23 plots the latency in terms of the time between a

Figure 22: Two of our battery-free nodes are attached to the doorframe and harvest energy from ambient light. Thanks to Bonito, the nodes can communicate in a timely and reliable fashion, allowing them to count the number of people entering and leaving the room.

		Ground truth		
		In	Out	No event
	In	30	0	1
Recorded	Out	0	31	0
	No event	1	0	0

Table 2: By collaborating, the battery-free nodes classified people entering and leaving the room with an average accuracy of 96.83 %.

Figure 23: Due to the low communication latency provided by Bonito, the system reported detected events both timely and accurately.

Figure 24: Example trace from the occupancy monitoring case study. The system correctly classifies and reports events to the base station. With Bonito, the connection interval is chosen large enough to sustain outliers of the charging time in response to transient shadowing.

button press and the reception of the detected event at the base station. The median latency was 1.2 s and all events were reported within less than 2 s. Over the course of the experiment, the two nodes successfully exchanged 10.56 kB of application data for an application-level throughput of 28.38 B/s.

Fig. 24 shows a ten-second excerpt from the experiment. The markers indicate the charging times of the nodes. Solid vertical lines indicate button presses (ground truth); dashed vertical lines indicate when a event was received at the base station. We can observe that, right after the received out-event, node 1 reports an exceptionally high charging time of 210 ms. This happens when the shadowing by a person occurs while a node charges its capacitor: The shadowing reduces the energy input for a short time, which prolongs the recharge. Nevertheless, by keeping the connection interval at around 700 ms, Bonito provides a stable connection despite such dynamics.

7 Discussion

Bonito is the first connection protocol for battery-free devices. It enables two devices to communicate efficiently and reliably by dynamically adapting the connection interval to changes in the devices' energy availability. In this section, we discuss limitations and opportunities for extending Bonito.

From connections to networks. The ability to efficiently and reliably exchange data between two devices is the fundamental building block required to form large wireless networks consisting of multiple battery-free devices. A number of tradeoffs and challenges arise from each of the possible approaches to move from the two-node setting to larger networks, which could be explored by future work. For example, devices may sequentially connect with their neighbors or devices may try to establish Bonito connections with one common connection interval between multiple devices.

Communication with battery-powered devices. While we focus on communication between two battery-free devices, Bonito is also useful for effective communication from battery-

free to battery-powered devices. For example, a battery-free tag may want to transmit data to a user's smartphone or to a battery-powered gateway in a wireless sensor network. Because battery-powered devices are in control of their wake-up times, any connection interval works for them. Thus, instead of computing the inverse joint cdf of the charging time distribution of both devices, it is sufficient to compute the inverse cdf of the charging time of the battery-free device in order to determine a connection interval that works for both devices.

Model accuracy. The goodness-of-fit of the learned charging time model critically affects the performance of Bonito. With perfect knowledge of the underlying distribution, Bonito would compute the minimum connection interval feasible for the requested target probability. Overestimating the real distribution leads to increased delay, while underestimation reduces reliability. If the distribution is so complex that a large number of model parameters or a non-parametric model (e.g., a deep neural network) would be required to accurately capture this complexity, then the limited resources on a battery-free device may not be sufficient to learn the model online.

Exploiting statistical dependence. In the current implementation, Bonito assumes statistical independence of the nodes' charging time distributions in order to compute a connection interval without prior knowledge of the statistical properties of the joint charging time distribution. After establishing a connection, the devices can record observations of the joint distribution and could attempt to exploit statistical dependence between their charging times, possibly improving communication efficiency and reliability.

8 Related Work

Intermittent computing. The thriving research area of intermittent computing has made great strides in recent years, including the first real deployments of battery-free sensors [1].

This achievement rests upon techniques that ensure forward progress [34], consistent peripheral state [6], and a reliable notion of time [11] despite frequent and random power failures. This line of research is highly relevant but completely orthogonal to our work as it deals exclusively with intermittency issues on *individual* devices and, if at all, considers communication with continuously powered base stations [42].

Battery-free device-to-device communication. Prior work on battery-free wireless device-to-device communication is mainly theoretical [24, 30, 50], studying the energy trade-offs for different scheduling, transmission, and decoding policies. Recent work discusses middleware and applications for networks of intermittently powered devices, yet explicitly leaves the question of how to communicate between the devices as an open problem [28, 48]. A simulative study also acknowledges the sheer difficulty of sychronizing the wake-up times of intermittently powered devices and proposes to communicate an energy state via an always-on backscatter radio, without demonstrating a real implementation or experiments [45]. Similar to Bonito, a recent theoretical work proposes to let nodes agree on a future point in time when they become active to increase communication throughput [46]. This time is computed based on a moving average of previous charging times, whereas Bonito lets the user explicitly trade reliability against delay by taking into account the charging time distributions.

In terms of practical work, tag-to-tag backscatter communication has mainly focused on physical-layer issues and considers intermittency an orthogonal problem [29, 35, 38, 49]. Instead, the Find neighbor discovery protocol explicitly addresses the intermittency problem and shows that by delaying wake-ups by a random time battery-free nodes can encounter each other faster [19]. We use Find to bootstrap efficient and reliable device-to-device communication with Bonito. Concurrently to our work, a protocol was proposed and implemented that lets devices "die early" when no packet is received to preserve energy and maximize the number of wake-ups [13].

Delay-tolerant networking (DTN). DTN studies networks that are only intermittently connected because of, for example, node failures, mobile users, and power outages [4, 17]. Both DTN and Bonito have the same high-level goal: effective communication in intermittently connected networks. However, DTN and Bonito address orthogonal problems toward the same end goal. While DTN is concerned with forwarding, routing, naming, in-network storage, and optimization of node trajectories to generate encounters in the spatial domain, Bonito aims to generate encounters in the time domain between nodes that are spatially close to each other. Whether concepts from the DTN literature could be applied on top of Bonito is an interesting question for future research.

Energy-aware MAC protocols. Numerous MAC protocols have been proposed for ad-hoc and sensor networks [15]. These protocols turn the radio off most of the time, and power it up only to send or receive a packet. The goal is to achieve a desired network lifetime by maintaining a certain average duty cycle. A fundamental assumption of these protocols is that the radio can be powered up *at any point in time*, which is exploited to reduce idle listening by flexibly scheduling communication among nodes. This is, however, not possible in a battery-free system, where devices are unavailable whenever the capacitor voltage is below a certain threshold, which renders existing energy-aware MAC protocols ineffective.

9 Conclusions

We have presented Bonito, a connection protocol for wireless battery-free devices. By adapting the connection interval to the different and time-varying charging times of intermittently powered nodes, Bonito maintains long-running connections that provide significantly better throughput, latency, and reliability than the state of the art. We have evaluated Bonito by implementing it on a battery-free prototype, conducting testbed experiments with real energy-harvesting traces from diverse scenarios, and demonstrating its utility in an occupancy monitoring case study. With Bonito, we contribute a prime communication primitive, device-to-device unicast, that brings the capabilities of battery-free systems one step closer to those known from today's battery-supported systems.

A Appendix: Gradient Equations

Exponential distribution. The derivative of the log-likelihood function is given by:

$$\mathcal{L}(\lambda) = \log\left(\lambda \cdot \exp(-\lambda x)\right) = \log \lambda - \lambda x_i \qquad (12)$$

$$\nabla \mathcal{L}(\lambda) = \frac{1}{\lambda} - x_i \qquad (13)$$

Calculating the *natural gradient* by defining the step size in terms of the Kullback-Leibler divergence in the distribution space has been shown to speed up convergence in many cases [2]. We obtain the natural gradient by multiplying the regular gradient from (13) with the inverse of the Fisher Information Matrix of the exponential distribution M_{exp}:

$$M_{exp} = \lambda^{-2} \tag{14}$$

$$\frac{\partial \mathcal{L}}{\partial \lambda} = [M_{exp}]^{-1} \cdot \frac{1}{\lambda} - x_i = \lambda - \lambda^2 \cdot x_i \tag{15}$$

Gaussian mixture model. We adopt the gradient equations from [44]: Let $f(x_i, \mu, \sigma^2)$ be the probability density function of the standard normal distribution. The responsibility function $r(x_i, k)$ quantifies the contribution of the k-th component to the model:

$$r(x_i, k) = \frac{\rho_k \cdot f(x_i, \mu_k, \sigma_k^2)}{\sum_l^K \left(\rho_l \cdot f(x_i, \mu_l, \sigma_l^2) \right)} \tag{16}$$

The update equations for the model parameters for the k-th component are then:

$$\frac{\partial \mathcal{L}}{\partial \rho_k} = r(x_i, k) - \rho_k \tag{17}$$

$$\frac{\partial \mathcal{L}}{\partial \mu_k} = \frac{1}{\rho_k} \cdot r(x_i, k) \cdot (x_i - \mu_k) \tag{18}$$

$$\frac{\partial \mathcal{L}}{\partial \sigma_k^2} = \frac{1}{\rho_k} \cdot r(x_i, k) \cdot (x_i - \mu_k)^2 - \sigma_k^2 \tag{19}$$

Normal distribution. We consider the special case of a gaussian mixture model with a single component and also use the equations from [44]:

$$\frac{\partial \mathcal{L}}{\partial \mu} = (x_i - \mu) \tag{20}$$

$$\frac{\partial \mathcal{L}}{\partial \sigma^2} = (x_i - \mu)^2 - \sigma^2 \tag{21}$$

Figure 1: Saiyan empowers the LoRa backscatter tag to demodulate feedback signals from a remote access point.

Abstract

The radio range of backscatter systems continues growing as new wireless communication primitives are continuously invented. Nevertheless, both the bit error rate and the packet loss rate of backscatter signals increase rapidly with the radio range, thereby necessitating the cooperation between the access point and the backscatter tags through a feedback loop. Unfortunately, the low-power nature of backscatter tags limits their ability to demodulate feedback signals from a remote access point and scales down to such circumstances.

This paper presents Saiyan, an ultra-low-power demodulator for long-range LoRa backscatter systems. With Saiyan, a backscatter tag can demodulate feedback signals from a remote access point with moderate power consumption and then perform an immediate packet re-transmission in the presence of packet loss. Moreover, Saiyan enables rate adaption and channel hopping – two PHY-layer operations that are important to channel efficiency yet unavailable on long-range backscatter systems. We prototype Saiyan on a two-layer PCB board and evaluate its performance in different environments. Results show that Saiyan achieves 3.5–5× gain on the demodulation range, compared with state-of-the-art systems. Our ASIC simulation shows that the power consumption of Saiyan is around 93.2 μW. Code and hardware schematics can be found at: https://github.com/ZangJac/Saiyan.

1 Introduction

Backscatter radios have emerged as an ultra-low-power and economical alternative to active radios. The ability to communicate over long distances is critical to the practical deployment of backscatter systems, particularly in outdoor scenarios (*e.g.*, smart farm) where backscatter tags need to deliver their data to a remote access point regularly. Conventional RFID technology [12] functions within only a few meters

and is not well suited for outdoor scenarios. To this end, the research community has proposed long-range backscatter approaches [23, 40, 47] that leverage Chirp Spreading Spectrum (CSS) modulation on LoRa [5] to improve the signal resilience to noise, thereby extending the communication range. For instance, LoRa backscatter [47] allows tags to communicate with a source and a receiver separated by 475 m.

However, existing long-range LoRa backscatter systems present a new challenge on packet delivery. The backscatter signals travel twice the link distance and suffer drastic attenuation as the link distance scales. They become very weak after traveling long distances, thereby causing severe bit errors and packet losses. Figure 2 shows the Bit Error Rate (BER) of PLoRa [40] and Aloba [23], two representative long-range LoRa backscatter systems. Evidently, the BER of both systems rises rapidly from less than 1% to over 50% as the tag is moved away from the transmitter (Tx). The receiver is almost unable to demodulate any backscatter signal once the tag is placed 20 m away from the transmitter. Considering that the backscatter tags are unaware of packet loss, each packet must be transmitted blindly for multiple times to lift the packet delivery ratio, which inevitably wastes precious energy and wireless spectrum and cause interference to other radios that work on the same frequency band.

To address these issues, we expect a *downlink* from the access point to the backscatter tag, through which the feedback signals (*e.g.*, asking for a packet re-transmission) can be delivered, thereby forming a *feedback loop*. We envision that such a feedback loop will bring opportunities to bridge

---

Yuan He is the corresponding author.

the gap between long-range backscatter communication and the growing packet loss rate, as reflected on the following aspects:

• *Making on-demand re-transmissions in the presence of packet loss*. The backscatter tag demodulates feedback signals from an access point and makes a re-transmission only if it is asked to do so. This reactive packet re-transmission can mitigate packet loss while improving power and channel efficiency.

• *Scheduling channel hopping to minimize interference*. The unlicensed band where the LoRa resides in is already over crowded. The access point monitors the wireless spectrum and notifies the backscatter tag to switch channels in the presence of in-band interference. As such, the channel utilization and packet delivery ratio can be improved effectively.

• *Adapting data rate to link condition*. The condition of backscatter links varies over time. The access point assesses each backscatter link and keeps the backscatter tag updated through the feedback loop. Each tag then adapts its data rate proactively to utilize the wireless link better.

In addition, such a feedback loop empowers the network administrator to turn on/off sensors on backscatter tags remotely, thereby avoiding labor-intensive and time-consuming physical access to the devices.

To enjoy these benefits, the primary hurdle to overcome is the packet demodulation on LoRa backscatter tags. LoRa is based on frequency modulation. To demodulate a LoRa symbol, the commercial LoRa receiver operates by down-converting the incident LoRa chirp to the baseband, sampling it at twice the chirp bandwidth (BW), and then converting the signal samples from the time domain to the frequency domain using Fast Fourier Transformation (FFT). These operations consume over 40 *mW* power altogether [6]. Considering a miniaturized energy harvester equipped with a palm-sized solar panel, this harvester merely generates 1 *mW* power every 25.4 seconds in a bright day [3]. In other words, to support the standard LoRa demodulation, a backscatter tag needs to wait for 17 minutes until it accumulates enough power. Although the envelope detector has been used for packet demodulation on many backscatter systems [38, 46, 52], it is ill-suited for LoRa demodulation because the envelope of a LoRa signal is a constant.

In this paper, we propose Saiyan, a low-power demodulator for long-range LoRa backscatter systems. Saiyan is based on an observation that *a frequency-modulated chirp signal can be transformed into an amplitude-modulated signal using a differential circuit*. The amplitude of this transformed signal scales with the frequency of the incident chirp signal, thereby allowing us to demodulate a LoRa chirp by tracking the peak amplitude on its transformed counterpart without using power-intensive hardware, such as a down-converter and an ADC. To put this high-level idea into practice, the challenges in design

Figure 2: BER of PLoRa [40] and Aloba [23] in different tag-to-transmitter settings. The BER of both systems rises dramatically with the increasing distance between the transmitter and the tag. We re-implement both systems on PCB.

and implementation must be addressed, as summarized below.

Frequency-amplitude transformation. The low-power nature of backscatter tags requires the differential circuit to be extremely low-power. Moreover, to support higher data rate, such a differential circuit should also be hyper-sensitive to the frequency variation of LoRa signals. However, the narrow bandwidth of LoRa signals (*e.g.*, 125/250/500 KHz) renders the conventional detuning circuits, such as RLC resonant circuit, inapplicable. In Saiyan, we instead repurpose the Surface Acoustic Wave (SAW) filter as a signal converter by leveraging its sharp frequency response (§2.1). To minimize the power consumption on demodulation, we further replace the power-consuming ADC with a well-designed double-threshold based comparator (§2.2) coupled by a proactive voltage sampler (§2.3).

Improving the demodulation sensitivity. Although the aforementioned vanilla Saiyan can demodulate LoRa signals with the minimum power consumption, its communication range is limited to 55 m because of the Signal-to-Noise Ratio (SNR) losses in both SAW filter and envelope detector. To extend the communication range, we introduce a low-power cyclic-frequency shifting circuit coupled with an Intermediate Frequency (IF) amplifier to simultaneously remove the noise while magnifying the signal power. This low-power circuit brings 11 dB SNR gain and doubles the demodulation range (§3.1). Furthermore, a low-power correlator is leveraged to extend the demodulation range further to 148 m (§3.2).

Implementation. We implement Saiyan on a 25 *mm*×20 *mm* two-layer Printed Circuit Board (PCB) using analog circuit components and an ultra-low power Apollo2 MCU [13]. The Application Specific Integrated Circuit (ASIC) simulation shows that the power consumption can be reduced to 93.2 *μW*, which is affordable on an energy harvesting tag. The main contributions of this paper are summarized as follows:
• We simplify the standard LoRa demodulation from energy perspective and design the first-of-its-kind low-power LoRa demodulator that can run on an energy harvesting tag.
• We design a set of simple but effective circuits and algorithms, prototyping them on PCB board for system evaluation.

- We demonstrate that Saiyan outperforms the state-of-the-arts on power consumption, communication range, and throughput.

The remainder of this paper is structured as follows. We present the design of vanilla Saiyan in Section 2, followed by super Saiyan in Section 3. Section 4 describes the implementation details. The experiment (§5) follows. We review related works in Section 6 and conclude in Section 7.

2 Vanilla Saiyan

A LoRa symbol is represented by a chirp whose frequency grows linearly over time, as formulated below.

$$s(t) = A sin(2\pi f(t)t) \tag{1}$$

where A is the signal amplitude; $f(t) = F_0 + kt$ describes how the frequency of this chirp signal varies over time; F_0 is the initial frequency offset; k is the frequency changing rate. The frequency of a LoRa chirp wraps to 0 right after peaking BW—the bandwidth of LoRa. Different LoRa chirps peak the frequency BW at different time due to the difference in their initial frequency offset, as shown in Figure 3(a). Applying a differential to a LoRa chirp, we have:

$$s'(t) = \frac{ds(t)}{dt} = A cos(2\pi f(t)t)[2\pi \frac{df(t)}{dt} t + 2\pi f(t)] \tag{2}$$
$$= \underbrace{2\pi A(F_0 + 2kt)}_{Amplitude} cos(2\pi f(t)t)$$

The above equation indicates that the amplitude of the transformed signal $s'(t)$ is proportional to the frequency of the input LoRa chirp $s(t)$, as shown in Figure 3(b). This frequency-amplitude correlation allows us to demodulate the frequency-modulated (FM) chirp signal by tracking the peak amplitude of its transformed amplitude-modulated (AM) counterpart.

2.1 Frequency-amplitude Transformation

To realize the differential operation [10], an intuitive solution is using RLC resonant circuit. However, the narrow bandwidth of LoRa (*e.g.*, 125/250/500 KHz) renders this idea infeasible (see Appendix A.1 for details). In Saiyan we instead exploit the sharp frequency response of the Surface Acoustic Wave (SAW) filter to transform LoRa chirps into amplitude-modulated signals.

SAW filter primer. A SAW filter consists of two interdigital transducers (shown in Figure 4). The input interdigital transducer transforms electrical signals into acoustic waves; the output interdigital transducer then transforms acoustic waves back into electrical signals. This two-stage signal transformation introduces 6 dB insertion loss to the incident signal [4].

Re-purposing SAW filter as a signal converter. Our design is based on the observation that the frequency response of a

Figure 3: LoRa symbols before and after frequency-amplitude transformation. (a) Different LoRa symbols in the frequency domain. (b) The amplitude of LoRa symbols after frequency-amplitude transformation.

Figure 4: Diagram of the SAW filter. The SAW filter converts electrical signal into acoustic signal and then back through two inter-digital transducers.

SAW filter grows monotonically within a certain frequency band (termed as *critical band*). After passing through the critical band, the chirp signal will be transformed into an AM signal whose amplitude scales with the frequency of this input FM chirp. This allows us to demodulate LoRa chirp by simply tracking the peak amplitude of the AM signal. On the other hand, since SAW filter by its own design is battery-free, such frequency-amplitude transformation doesn't incur extra power consumption to backscatter tags.

In Saiyan, we take into account the working frequency and bandwidth of LoRa signals and select a general-purpose Qualcomm B3790 [1] SAW filter as the signal converter. Figure 5 shows its frequency response. The signal amplitude grows by 25 dB as the frequency of the incident signal scales from 433.5 MHz to 434 MHz (500 KHz bandwidth). To validate this 25 dB amplitude gap is strong enough for differentiating LoRa chirps, we feed four different chirp symbols into this SAW filter and plot the output in Figure 6. Evidently, these symbols peak their amplitude at clearly different time points, confirming the effectiveness of the SAW filter.

2.2 Demodulation

The transformed symbols are down-converted to the baseband through an envelope detector. Before demodulation, the
Figure 5: The amplitude-frequency response of the SAW filter adopted by Saiyan. The central frequency is 434 MHz. The measured insertion loss of this SAW filter is 10 dB. We observe 25 dB, 9.5 dB, and 7.2 dB amplitude variation as the frequency of an incident signal grows from 433.5 MHz, 433.75 MHz, and 433.875 MHz to 434 MHz, respectively.

standard LoRa receiver first digitizes these baseband signals using an ADC, which is power intensive. To save power, an intuitive solution is to replace the ADC with a low-power voltage comparator [37, 46]. The threshold of this comparator is set to a value slightly lower than the peak amplitude of the basband signal. This allows us to locate the peak amplitude by checking the comparator's output. Unfortunately, due to the in-band interference and hardware noise, the transformed AM signal may experience multiple amplitude peaks and valleys that may confuse the comparator.

Double-threshold based comparator. In Saiyan we instead adopt a double-threshold based comparator to stabilize the output binary sequence. Let U_H and U_L denote the high-voltage and low-voltage threshold defined in this comparator. When the amplitude of an input signal is sufficiently higher than U_H, the comparator outputs a high voltage. When the amplitude of this signal is equivalent to U_H or above, no chattering occurs since the output will not respond unless the input falls below U_L. Following this idea, the output voltage B_i can be formulated as follows:

$$B_i = \begin{cases} low, & if \quad A_i < U_H \quad \& \quad B_{i-1} = low \\ high, & if \quad A_i \geq U_H \quad \& \quad B_{i-1} = low \\ low, & if \quad A_i < U_L \quad \& \quad B_{i-1} = high \\ high, & if \quad A_i \geq U_L \quad \& \quad B_{i-1} = high \end{cases} \quad (3)$$

where A_i represents the amplitude of the ith signal sample. This double-threshold comparator takes into account the amplitude samples both in the past and present. It nulls out the chattering caused by the amplitude oscillation. The threshold setup is detailed in system implementation (§4).

To show the effectiveness of this double-threshold based comparator, we apply it to a LoRa chirp and plot the output in Figure 7. For comparison, we also plot the output of two single-threshold based comparators (U_H alone and U_L alone, respectively). We can see that using a high threshold U_H

Table 1: The required sampling rate (KHz) in theory/practice to achieve 99.9% decoding accuracy.

K=5	250/400	125/180	62.5/85	31.2/40	15.6/20	7.8/12

alone fails to detect the amplitude peak due to the valleys emerging on signal amplitude (*i.e.*, $t \in [t_E, t_F]$ in Figure 7(b)). Using a low threshold U_L alone causes false positives due to the misleading peak emerging on the signal amplitude ($t \in [t_A, t_B]$ in Figure 7(d)). In contrast, the double-threshold based comparator produces a series of stable binary voltages that can guide us to locate the peak amplitude at the correct position (*i.e.*, at the tail of the high voltage samples t_F shown in Figure 7(e)).

2.3 Low-power Voltage Sampler

The comparator quantizes chirp samples into binary voltages which are stored in a counter of micro-controller (MCU). The sampling rate tradeoffs the power consumption and the demodulation performance and thus cannot be set arbitrarily. A higher sampling rate supports a higher link throughput. It however consumes more power. Suppose a LoRa chirp encodes K bits data. The data rate equals $K \cdot BW / 2^{SF}$, where BW and SF respectively represent bandwidth and spreading factor. According to the Nyquist sampling theorem, the sampling rate should be not lower than $2 \cdot BW / 2^{SF-K}$.

However, in reality, using the theoretical minimum sampling rate exacerbates bit errors. We conduct a benchmark experiment to measure the practical sampling rate required to achieve 99.9% decoding accuracy. Table 1 lists the results with different settings of spreading factor and coding rate. We find that the required sampling rate in practice is slightly higher than the theoretical minimum sampling rate. Suggested by this result, we conservatively set the sampling rate to $3.2 \cdot BW / 2^{SF-K}$, which guarantees the demodulation performance.

Decoding. After quantization, the low-power MCU decodes each LoRa chirp by localizing the bit '1' within each LoRa symbol, as shown in Figure 8. The LoRa preamble contains ten identical up-chirps. Upon detecting the LoRa preamble, Saiyan waits for 2.25 symbol times (sync. symbols) and operates demodulation on the payload hereafter.

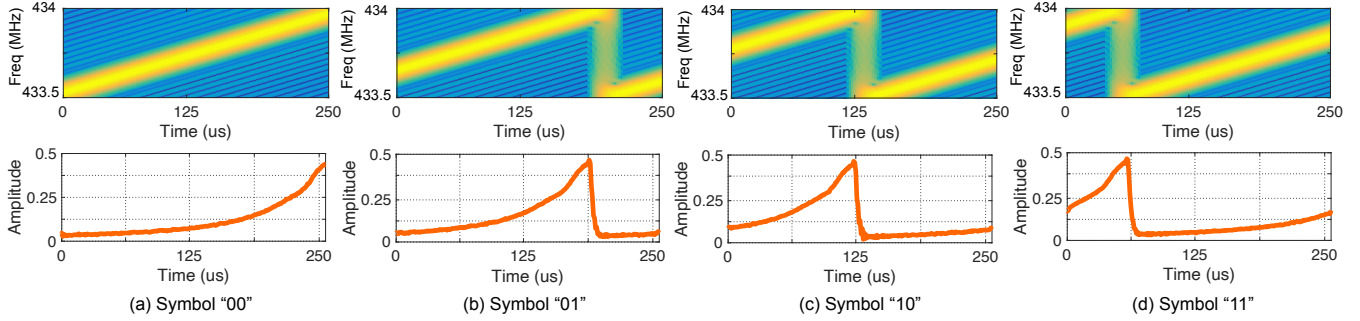
Remarks. The vanilla Saiyan demodulates LoRa signals with the minimum power consumption. However, its demodulation sensitivity is limited due to the signal attenuation in the SAW


Figure 6: The input (top) and output (bottom) signals of the SAW filter. The amplitude of the output signal scales with the frequency of the input signal. They reach the maximal value simultaneously.

Figure 7: Comparing the output of different voltage comparators. (a): the incident LoRa chirp. (b): the output of an envelope detector. filter and the noise added by the envelope detector. Next, we introduce super Saiyan to improve the sensitivity.

3 **Super** Saiyan

Super Saiyan takes the following actions to consistently improve the demodulation sensitivity: *i*) improving the SNR of baseband chirp signals with a cyclic-frequency shifting circuit, and *ii*) improving the sensitivity of demodulator with correlation.

3.1 Cyclic-frequency Shifting

Understanding the principle of envelope detector. The envelope detector has been widely adopted by low-power RF devices to down-convert the incident signal. However, due to the inherent non-linearity caused by the squaring operation of

Figure 8: The decoding process of a LoRa packet

CMOS devices [27], both the targeted signal (*i.e.*, feedback signals from the LoRa access point) and the RF noises will be down-converted to the baseband. Consequently, the targeted signal becomes even weaker after down-conversion. We explicate this phenomenon using the following example. Let S_{in} be the incident signal: $S_{in} = S_t + S_n$, where S_t and S_n denote the targeted signal and RF noises, respectively. The output signal S_{out} of this envelope detector can be represented by:

$$S_{out} = kS_{in}^2 = k(S_t + S_n)^2 \qquad (4)$$
$$= kS_t^2 + 2kS_t \cdot S_n + kS_n^2$$

where k represents the attenuation factor. The first term S_t^2 on the right side of this equation manifests that the targeted signal S_t is shifted to the baseband through self-mixing. The second and the third terms both indicate the RF noises are shifted to the baseband after mixed with the targeted signal and the noises themselves, respectively, causing strong interference on the baseband.

Cyclic-frequency shifting. In Saiyan we design a low-power circuit to mitigate the SNR loss brought by the envelope detector. The circuit is realized by two RF mixers and two clock signals. Its operation is detailed as follows.

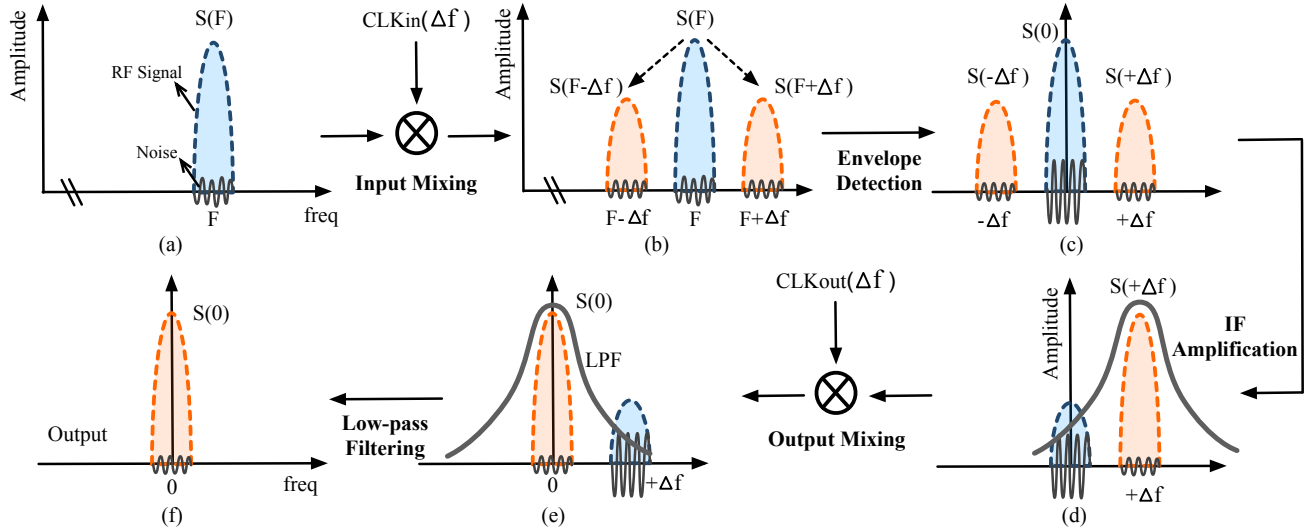
• **Step 1**. The micro-controller first generates a clock signal $CLK_{in}(\Delta f)$ and mixes it with the incident signal $S(F)$, resulting in two sideband signals $S(F - \Delta f)$ and $S(F + \Delta f)$, as shown in Figure 9(a)-(b). The sideband signals and the


Figure 9: The illustration of the cyclic-frequency shifting. (a) The input signal $S(F)$. (b) $S(F)$ is first mixed with the clock signal, resulting in two sideband signals $S(F-\Delta f)$ and $S(F+\Delta f)$. (c) The envelope detector extracts the envelope of those three signals and down-converts them to the the baseband. (d) The IF amplifier boosts the power of $S(\Delta f)$ and attenuates the power at other frequency bands. (e) The desired signal $S(\Delta f)$ with significantly lower noises is shifted back to the baseband. (f) The output signal $S(0)$.

incident signal are then down-converted to the intermediate frequency (IF) band (denoted by $S(-\Delta f)$ and $S(\Delta f)$) and the baseband (denoted by $S(0)$) respectively with an envelope detector (Figure 9(c)).

• **Step 2**. Since RF noises are not down-converted to the IF band by the envelope detector, we amplify the unpolluted IF signal $S(\Delta f)$ using a low-power IF amplifier. The frequency selectivity of this IF amplifier filters out signals at other frequencies (*e.g.*, $S(0)$), as shown in Figure 9(d).

• **Step 3**. The power-amplified IF signal $S(\Delta f)$, mixed with another clock signal $CLK_{out}(\Delta f)$, is shifted back to the baseband, as shown in Figure 9(e). At the same time, the noisy baseband signal $S(0)$ will be shifted to the IF band and then filtered by a low-pass filter (Figure 9(f)).

In a nutshell, this circuit first moves the targeted signal to an intermittent frequency band (step 1) to avoid the RF noise contamination introduced by the envelope detector. This also leaves us an opportunity to remedy the SNR loss in down-conversion (step 2). Finally, the targeted signal is moved back to the baseband for demodulation. At the same time the DC offset, flicker and other noises are moved to the IF band and removed by a low-pass filter (step 3).

Figure 10 shows the spectrums before and after feeding the chirp signal into the cyclic frequency shifting circuit. Evidently, both the inband and out-of-band RF noises have been cleaned by the circuit, ensuring the decodability of chirp signals. Our quantitative measurement shows that the cyclic-frequency shifting circuit brings in 11 dB SNR gain.

Clock signal generation. The above circuit design relies on two clock signals $CLK_{in}(\Delta f)$ and $CLK_{out}(\Delta f)$. To save power,

Figure 10: The spectrum of an incident LoRa signal when being down-converted into the baseband with an envelope detector. (a) Without cyclic-frequency shifting. (b) With cyclic-frequency shifting. The LoRa signal contains 24 LoRa chirps (*BW*=500KHz, *SF*=8).

we program the MCU to generate $CLK_{in}(\Delta f)$ signal and then leverage a delay line to copy $CLK_{in}(\Delta f)$ as $CLK_{out}(\Delta f)$:

$$CLK_{out}(\Delta f) = CLK_{in}(\Delta f + \Delta \phi) \tag{5}$$

where $\Delta \phi$ is the phase shift caused by the delay line. We tune the length of this delay line to ensure $cos(\Delta \phi) \approx 1$ so that $CLK_{out}(\Delta f)$ equals $CLK_{in}(\Delta f)$.

Circuit integration. We integrate this cyclic-frequency shifting circuit into the envelope detector. Figure 11 shows the schematic of this design. It consists of an input mixer, an output mixer, an envelope detector, an IF amplifier, a low-pass filter (LPF), an oscillator, and a transmission line. Specifically, The base clock signal is provided by a micro-power precision oscillator LTC6907 [11]. A low-power transistor 2N222 [8] is adopted as the IF amplifier.
Figure 11: The schematic of cyclic-frequency shifting.

Figure 12: The high-level circuit schematic of Saiyan.

3.2 Correlation

While the above cyclic-frequency shifting circuit successfully improves the SNR of the incident signal, the demodulation accuracy still suffers degradation when the incident signal is too weak, *e.g.*, close to the noise floor. We thus employ correlation — a mainstream approach that has been largely adopted for packet detection to further improve the demodulation sensitivity. It operates by correlating signals samples with a local chirp template. An energy peak shows up as long as the incident signal matches the template. The receiver then tracks the energy peak and demodulates the incident signal.

4 Implementation

We describe the system implementation in this section.

4.1 Backscatter Tag

We implement Saiyan on a 25 *mm*×20 *mm* two-layer PCB using commercial off-the-shelf analog components and an ultra-low power Apollo2 (10 *μ*A/MHz) [13] MCU. We determine its size through a mixed analytical and experimental approach, striking a balance between the form factor and circuit interference. Figure 13 shows the hardware prototype. Saiyan functions with an omni-directional antenna [2] with 3 dBi gain.

Architecture and workflow. Figure 12 shows the architecture of Saiyan. The incident signal passes through a passive SAW chip B39431B3790Z810 [1] and is transformed into an amplitude-modulated signal. We place a common-gate low-noise amplifier (CGLNA) [17] between the SAW filter and the customized envelope detector to amplify the transformed signal. The amplified signal is then down-converted to the baseband through the envelope detector. Finally, a low-power voltage comparator NCS2202 [9] is leveraged to quantize the output signal from the envelope detector.

Figure 13: The hardware prototype of Saiyan. The quarter next to Saiyan demonstrates the form factor.

Plug-and-play. As an ultra-low-power peripheral, Saiyan can be integrated into the existing long-range LoRa backscatter systems [23, 40] with ignorable engineering efforts. Taking PLoRa [40] as an example, we replace its packet detection module with Saiyan and retained all the remaining functional units the same. This simple replacement allows PLoRa tag to demodulate the feedback signals while retaining the modulation capability at the same time. On the software side, we replicate the sampling rate control logic to facilitate the demodulation.

Power management. The energy harvester on Saiyan comprises of a palm-sized photovoltaic panel and a high-efficiency step-up DC/DC converter LTC3105 [3]. It generates 1 *mW* power every 25.4 seconds in a bright day. The power management module provides a constant 3.3V output voltage to the MCU. The power consumption of this power management module in working mode is approximately 24 *μW*

Determining the voltage thresholds U_H and U_L. Ideally, U_H should be slightly lower than the peak amplitude of the input signal A_{max}. Let G be the gap between A_{max} and the voltage threshold U_H. We have: $G = 20lg(A_{max}/U_H)$. Thus, U_H can be estimated on the basis of the following equation: $U_H = A_{max}/10^{\frac{G}{20}}$. The threshold voltage U_L is set to $U_H - U_F$, where U_F represents the amplitude of the envelope detector's output. The thresholds U_H and U_L are tuned by two adjustable on-board resistors. In practice, considering that A_{max} and U_F both vary with the link distance, we measure these two values offline under different link distance settings and store a mapping table on each tag to facilitate the configuration of U_H and U_L. To alleviate this manual configuration overhead, one could leverage an Automatic Gain Control (AGC) [42, 43] to adapt the power gain automatically. We leave it for future work.

4.2 LoRa Transmitter and Receiver

LoRa transmitter. We use two types of LoRa transmitters in the evaluation: *i*) a LoRa transmitter implemented on a software-defined radio platform USRP N210, and *ii*) a com-

Figure 14: Outdoor experiment field.

mercial off-the-shelf LoRa node equipped with a Semtech SX1276RF1JAS [7] chip. Both platforms use a single omnidirectional antenna with 3 dBi gain. The transmission power is set to 20 dBm.

LoRa receiver. The LoRa receiver is implemented on a software-defined radio platform USRP N210. We set the sampling rate to 10 MHz, thereby allowing the receiver to monitor six LoRa channels simultaneously.

4.3 ASIC Simulation

We simulate the Application Specific Integrated Circuit (ASIC) of Saiyan based on the TSMC 65-nm CMOS process. The active area of on-chip Integrated Circuits (IC) is $0.217 \ mm^2$. The ASIC simulation shows that the power consumption of Saiyan is 93.2 μW. Specifically, the power consumption of LNA, oscillator, and digital circuit is 68.4 μW and 22.8 μW, and 2 μW, respectively. Once Saiyan demodulated the feedback signals, the MCU starts preparing data for packet re-transmissions, which consumes extremely low power (*i.e.*, the power consumption of the ultra-low power Apollo2 [13] in Saiyan is merely 19.6 μW).

4.4 MAC-layer for Multi-tag Coexistence

We briefly discuss MAC-layer in this section. The downlink packets can be divided into three groups: unicast packet, multicast packet, and broadcast packet. In unicast, all backscatter tags within the radio range will receive and demodulate this unicast packet from the access point. However, only the targeted tag will response (*e.g.*, re-transmit the lost packet). Hence, no collision occurs. However, in multicast and broadcast, collision happens as long as more than one backscatter tag replies at the same time. For instance, the access point sends a downlink packet (*e.g.*, turn off the humidity sensor), while multiple tags acknowledge the reception of this downlink packet simultaneously. In this case, the access point can leverage slotted ALOHA [22] protocol to coordinate tags and minimize collisions. We take Figure 15 as an example to illustrate the MAC-layer operation. Suppose three tags are sending an acknowledgement to the access point to confirm the reception of a downlink packet. Each tag will randomly select a time slot and store it in its local counter. Upon the

Figure 15: The illustration of MAC-layer operations in Saiyan. Each tag randomly selects a slot to transmit. The access point (AP) signals the beginning of each slot with a carrier signal.

detection of a carrier signal from the access point, each tag decreases the slot number by one and transmits as soon as the slot number goes zero. The randomness in slot selection minimizes the interference among tags.

5 Evaluation

In this section, we present the evaluation results of field studies (§5.1) and micro-benchmarks (§5.2). Two case studies follow (§5.3). Unless otherwise posted, the transmitter and the receiver are collocated throughout the experiment.

Setups. The LoRa transmitter works on the 433.5 MHz frequency band. The spreading factor and the bandwidth are set to 7 and 500 KHz, respectively. The payload of each LoRa packet contains 32 chirp symbols. In each experiment, we let the transmitter transmit 1,000 LoRa packets and then repeat the experiment for 100 times to ensure the statistical validity. We adopt *BER*, *throughput*, and *demodulation range* as the key metrics to assess Saiyan's performance.

- **BER** refers to the ratio of error bits to the total number of bits received by Saiyan.

- **Throughput** measures the amount of received data correctly decoded by Saiyan within one second.

- **Demodulation range** refers to the maximum distance between the tag and the LoRa transmitter when the BER is maintained below 1‰.
5.1 Field Studies

We conduct field studies both indoors and outdoors to assess the impact of coding rate (CR), spreading factor (SF), and bandwidth (BW) on BER, demodulation range, and throughput, which are three key evaluation metrics.
5.1.1 Outdoor experiments

Impact of coding rate. We place a Saiyan tag 10 m, 20 m, 50 m, 100 m, and 150 m away from a LoRa transmitter. Under
Figure 16: BER and throughput in different coding rate settings.

Figure 17: Demodulation range and throughput in different SF settings.

Figure 18: Demodulation range and throughput in different BW settings.

each distance setting, we vary the coding rate of LoRa signals and measure BER and throughput. We have three observations based on the results shown in Figure 16.

First, the BER grows with the coding rate. As shown in Figure 16(a), the BER under the highest coding rate setting (*i.e.*, 5) is 2.4–5.2× higher than the BER under the lowest coding rate setting (*i.e.*, 1) across all different Tx-to-tag distances. For instance, when the Tx-to-tag distance is 100 m, Saiyan achieves a BER of 1.85‰ under the highest coding rate setting. The BER then drops to 0.4‰ under the same Tx-to-tag distance setting when we change the coding rate to 1. This is expected since the Saiyan tag has to differentiate more types of LoRa chirps under the high coding rate setting.

Second, the throughput grows linearly with the coding rate (Figure 16(b)). For example, when the Tx-to-tag distance is 100 m, the achievable throughput at CR=5 (18.12 Kbps) is around 5.1× higher than the throughput at a coding rate of 1 (3.57 Kbps).

Third, both the BER and the throughput get exacerbated with the growing Tx-to-tag distance. For instance, when CR=5, the BER grows dramatically from 0.1‰ to 4.4‰ as the Tx-to-tag distance grows from 10 m to 150 m. The throughput, on the other hand, declines from 19.6 Kbps to 17.2 Kbps. This is expected since Saiyan relies on the signal power to demodulate the incident LoRa signal.

Impact of spreading factor. Next, we vary the spreading factor from 7 to 12 and assess Saiyan's demodulation range and throughput under each setting. The results are shown in Figure 17. We observe that the demodulation range grows with the increasing spreading factor. The throughput, on the contrary, declines with the increasing spreading factor. For instance, the demodulation range under the highest spreading factor setting (*i.e.*,SF=12) is 1.1–1.3× longer than the

demodulation range under the lowest spreading factor setting (*i.e.*, SF=7) across three different coding rate settings. The throughput drops by 30.3–35.1× as we decrease the SF from 12 to 7. This is expected since a higher spreading factor enhances the anti-noise capability of LoRa signals; thus the demodulation range grows. On the other hand, the symbol time grows with the increasing spreading factor, resulting in a lower throughput.

Impact of bandwidth. We set the spreading factor to 7 and assess the impact of LoRa bandwidth on the demodulation range and throughput. The results are shown in Figure 18. We observe that the demodulation range and the throughput both grow with the LoRa bandwidth. Specifically, given the coding rate of 2, the demodulation range grows from 72.2 m to 138.6 m as we increase the bandwidth from 125 KHz to 500 KHz. On the other hand, since the LoRa symbol time is inversely proportional to the bandwidth, we observe the throughput drops around 4× from 7.2 Kbps to 1.8 Kbps as we decrease the bandwidth from 500 KHz to 125 KHz.

5.1.2 Indoor experiments

We repeat the above experiments in an indoor environment where the LoRa signals have to penetrate one or multiple concrete walls to arrive at the backscatter tag.

Penetrating one concrete wall. Similar to the trend shown in the outdoor scenario, the throughput measured in the indoor scenario also grows with the increase of the coding rate (Figure 19). For example, the throughput grows from 3.7 Kbps to 18.7 Kbps when the coding rate varies from 1 to 5. The demodulation range, on the other hand, declines from 48.8 m to 26.2 m as we increase the coding rate from 1 to 5.

**Penetrating two concrete walls**. The LoRa signal experi-

Figure 19: Throughput and downlink range in the presence of one concrete wall.

Figure 20: Throughput and downlink range in the presence of two concrete walls.

Figure 21: Comparison of Saiyan, Aloba, and PLoRa on the detection range.

Figure 22: RSS and BER over distance.

Figure 23: The amplitude gap of the output signal after SAW filter

Figure 24: Demodulation range under different temperatures

ences stronger attenuation when penetrating two concrete walls. Accordingly, we observe the demodulation range and the throughput decline by 2.21-2.09× and 1.01-1.05× compared to those under the single concrete wall settings (Figure 20).

5.1.3 Comparison with state-of-the-art systems

We further compare Saiyan with two state-of-the-art systems, namely, Aloba [23] and PLoRa [40] in both outdoor and indoor environments. PLoRa operates cross-correlation to detect a LoRa packet. Aloba feeds the incident signal into a moving average filter and then leverages the unique RSSI pattern of the LoRa preamble to detect a LoRa packet. They both cannot demodulate the payload. Therefore, we compare them with Saiyan in terms of the packet detection range.

Figure 21 shows the experiment result. In the outdoor line-of-sight settings, Saiyan achieves a packet detection range of 148.6 m, outperforming ALoBa (30.6m) and PLoRa (42.4m) by 4.52× and 3.26×, respectively. In an indoor none-line-of-sight environment, although the packet detection range of Saiyan declines to 44.2 m, it still outperforms Aloba (12.4 m) and PLoRa (16.8 m) by 3.56× and 2.63×, respectively.

5.2 Micro-benchmarks

To better understand the performance of each design component in Saiyan, we run micro-benchmarks to assess the receiver sensitivity, the SAW filter, as well as the power consumption and the system cost.

5.2.1 Receiver sensitivity

We define the receiver sensitivity as the minimum Received Signal Strength (RSS) of an incident signal that can be detected by Saiyan. To assess the receiver sensitivity, we measure the BER and the Received Signal Strength (RSS) under different Tx-to-tag distance settings. As expected, the BER grows gradually with the increase of the Tx-to-tag distance, as shown in Figure 22. Nevertheless, Saiyan can still detect the incident signal when the tag is 180 m away from the transmitter. As we increase the tag-to-Tx further, the signal strength is too weak to be detected by Saiyan. The above experiment demonstrates an -85.8 dBm receiver sensitivity, outperforming the conventional envelope detector by 30 dBm [27].

5.2.2 Performance of the SAW filter

Frequency-amplitude response. Saiyan relies on the frequency-amplitude response of the SAW filter to demodulate LoRa signals. A sharp frequency-amplitude response (*e.g.*, a small frequency variation leads to a large amplitude gap) is desirable as it allows the Saiyan tag to detect the minute frequency variation on the incident signal.

We feed LoRa signals with different bandwidth into the SAW filter and measure the amplitude variation of the output signal. The results are shown in Figure 23. As expected, the amplitude variation of the output signal (*a.k.a.*, amplitude gap) tends to be less significant with the decreasing chirp bandwidth. For instance, when the Tx-to-tag distance is 10 m, the amplitude gap drops from 24.7 dBm to 9.3 dBm, and further to 7.1 dBm as we decrease the chirp bandwidth from 500 KHz to 250 KHz, and further to 125 KHz, respectively. A similar trend shows up as we increase the Tx-to-tag distance.
Figure 25: Ablation study of Saiyan.

Figure 26: PRR in different settings.

Figure 27: PRR lifts with Saiyan.

Table 2: Energy consumption (under 1% duty cycling) and cost of each component in Saiyan tag.

Component	SAW Filter	LNA	OSC Clock	Envelope Detector	Comparator	MCU	Total
Energy (μW)	0	248.5	86.8	0	14.45	19.6	369.4
Cost ($)	3.87	4.15	1.25	1.20	1.26	15.43	27.2

For instance, when the signal bandwidth is 500 KHz, the amplitude gap of the output signal drops from 24.7 dBm to 20.2 dBm as the Tx-to-tag distance increases from 10 m to 100 m.

The impact of temperature. The frequency selectivity of the SAW filter is affected by the ambient temperature [36]. We thus run an experiment to assess the impact of temperature on the demodulation range. The experiment is conducted outdoors on a sunny day from 8 a.m. to 8 p.m.. Figure 24 shows the result. We observe that the demodulation range in general is insensitive to the temperature. For instance, when the temperature rises from the lowest -8.6 °C at 8 a.m. to the highest 1.6 °C at 2 p.m., the demodulation range merely drops from 126.4 m to 118.6 m.

5.2.3 Ablation study

We conduct an ablation study to assess the effectiveness of each design component of Saiyan. In this experiment, we set the spreading factor and the bandwidth to 7 and 500 KHz respectively and measure the maximum demodulation range under different coding rate settings. The results are shown in Figure 25. We find that the vanilla Saiyan achieves a relatively short demodulation range (38.4 m—72.6 m) across five different coding rate settings. The demodulation range then grows by 1.56×–1.73× with the help of the cyclic frequency shifting module. The cross-correlation further improves the demodulation range by 1.94×–2.25×.

5.2.4 Power consumption & system cost

Table 2 summarizes the power consumption (under 1% duty cycling as in LoRa [22]) and cost of each component in Saiyan. Among these hardware components, the most power-hungry parts are LNA and oscillator (OSC) clock, which account for 67.3% and 23.5% of the total power consumption, respectively. As we demonstrate in §4.3, the power consumption can be effectively reduced by 74.8% when implementing Saiyan

on ASIC. The hardware cost of Saiyan, on the other hand, is around 27.2 USD, which can be also reduced sharply after ASIC fabrication.

5.3 Case Studies

Next, we run two real-world case studies to showcase packet re-transmission (§5.3.1) and frequency hopping (§5.3.2).

5.3.1 Packet re-transmission through the ACK mechanism

Setups. We integrate Saiyan into PLoRa and Aloba tags, which allows the tags to demodulate the feedback signals from the receiver and make an immediate packet re-transmission if needed. The link distance is set to 100 m.

Results. As shown in Figure 26, PLoRa and Aloba achieve 81.8% and 45.6% packet reception ratio (PRR) without packet re-transmission. The PRR of Aloba grows drastically from 45.6% to 70.1% when the Aloba tag is allowed to re-transmit the lost packet only once. The PRR then grows to 83.3$ and further to 95.5% when the Aloba tag re-transmits the lost packet twice and three times, respectively. The PRR of PLoRa shows the similar trend. These results demonstrate that Saiyan effectively improves the packet reception ratio for long-range LoRa backscatter systems.

5.3.2 Interference avoidance through channel hopping

As an ultra-low-power tag working on the ISM band, both PLoRa and Aloba are likely to bear strong in-band interference from other legacy RF devices working on the same band. We show that with Saiyan, these backscatter tags can demodulate the feedback signals from the receiver and switch to other channels to avoid interference.

Setups. We use PLoRa to demonstrate the feasibility of channel hopping. The PLoRa tag communicates with the receiver at the 434 MHz frequency band. It switches to the 434.5 MHz frequency band upon detecting the feedback signal from the receiver. We put a software-defined radio three meters away from the receiver to jam the channel at the 433 MHz frequency band.

Results. Figure 27 shows the CDF of PRR before and after the channel hopping. We can see the PRR is very low when the USRP jams the channel (dotted line). As the receiver

initiates a channel hopping command to the backscatter tag, we witness a significant lift on the PRR. In particular, the median PRR grows from 47% to 92% once PLoRa switches to another channel. This result clearly demonstrates that Saiyan can support better channel utilization through remote control.

6 Related Work

We review research topics relevant to Saiyan in this section.

RFID system. A passive RFID tag modulates sinusoidal tone from an RFID reader to transmit data [52, 58]. It can also demodulate amplitude-modulated (AM) signals from a nearby RFID reader [16, 26, 51, 53]. Specifically, the RFID tag downconverts the incident signal to the baseband and accumulates the signal power through an integrator circuit. Subsequently, it compares the accumulated power to a threshold to demodulate incident signals. Saiyan differs from passive RFID tags in two aspects. First, Saiyan demodulates frequency-modulated signal as opposed to amplitude-modulated signal. Second, Saiyan is designed for long-range backscatter systems whereas the passive RFID tag functions within only a few meters.

Ambient backscatter systems. Ambient backscatter systems empower backscatter tags to take the ambient wireless traffic as the carrier signals [14, 15, 18, 20, 23, 29–33, 35, 37, 39, 40, 47–50, 55–57, 60]. For example, WiFi backscatter [33] reuses WiFi signals as the carrier, thereby allowing for the backscatter tag to communicate with a commercial WiFi receiver. Interscatter [29] enables backscatter tags to modulate Bluetooth signals into WiFi signals. LoRa backscatter [47] allows backscatter tags to communicate over long distances by taking advantage of the noise resilience of LoRa symbols. These pioneer works have remarkably improved the throughput and the communication range of backscatter systems. Some recent works [37, 44, 55, 56, 59, 60] support a few types of downlink functionalities such as carrier sensing [37, 44, 55, 56, 59, 60] and packet detection [23, 40] at the packet level. For example, WiFi backscatter [33], Passive-WiFi [34], Interscatter [29], LoRa backscatter [47], and Netscatter [24] use the presence and absence of carrier packets to convey downlink data. However, they cannot demodulate downlink packets at the symbol level, particularly under long-range settings. Saiyan can serve as an important building block to the existing long-range backscatter systems, where the on-demand retransmission is needed due to the drastic packet loss.

Low-power demodulator. With the growth of low-power IoT market, the research community has shifted the focus to the design and implementation of low-power RF receivers, *e.g.*, by replacing the active components with their passive counterparts, or by offloading the power-intensive functions to external devices. Ensworth et al. [19] proposed a 2.4 GHz low-power BLE receiver that offloads the RF local oscillator to an external device. Carlos et al. [41] proposed a low-power 802.15.4 receiver that could demodulate phase-modulated

ZigBee signals at orders of magnitude lower power consumption compared with the standard 802.15.4 receiver. However, the working range of this low-power receiver is limited to tens of centimeters, which sets a strong barrier towards the practical deployment. Turbo charging [39] designs a multi-antenna cancellation circuit to facilitate the signal demodulation on backscatter tags. Similarly, full-duplex backscatter [38] enables a backscatter tag to demodulate the instantaneous feedback signal from another backscatter tag. Saiyan differs from these systems in two aspects. First, Saiyan is designed for demodulating frequency-modulated signals as opposed to phase or amplitude modulated signals. Second, Saiyan can support up to 180 m demodulation range, whereas all the aforementioned systems function within only tens of centimeters.

SAW filter. The SAW filter has been widely adopted by wireless communication systems such as telecommunications [25], radar [54], and aerospace communications [45], *etc.* These systems leverage the low-distortion and minimal passband variation of the SAW filter to filter out noise and interference signals. Furthermore, medical devices transform a SAW filter into a sensor for in-situ detection (*e.g.*, detecting chemical gas concentration) [21, 28]. Different from all the above applications, Saiyan exploits the sharp frequency response of the SAW filter to demodulate frequency-modulated signal.

7 Conclusion

We have presented the design, implementation, and evaluation of Saiyan, the first-of-its-kind low-power demodulator for LoRa backscatter systems. Saiyan allows LoRa backscatter tags to demodulate the command or feedback signals from a remote access point that is hundreds of meters away. With such capability, the backscatter tag can realize a plethora of networking functionalities, such as packet re-transmission, channel hopping, and rate adaptation. Field study shows that Saiyan outperforms state-of-the-art systems by 3.5–5× in terms of demodulation range. The ASIC simulation shows that the power consumption of Saiyan is around 93.2 μW.

A Appendix

In this section, we prove the infeasibility of RLC resonant circuit to realize LoRa frequency-amplitude transformation.

A.1 The Infeasibility of RLC Resonant Circuit

The center frequency ω_0, the passband $\Delta\omega$, and the quality factor Q of a resonant circuit satisfy that:

$$Q = \frac{\omega_0}{\Delta\omega} \tag{6}$$

A higher Q value leads to a narrower passband width. Taking a step further, the quality factor Q is determined by the resistance R, inductance L, and capacitance C of this circuit following the equation:

$$Q = \sqrt{L}/(R \cdot \sqrt{C}) \tag{7}$$

Given a constant center frequency of $\omega_0 = 1/(2\pi\sqrt{LC})$, we can deduce the capacitance C satisfy that:

$$C = \frac{1}{Q\omega_0 R} = \frac{\Delta\omega}{\omega_0^2 R} \tag{8}$$

Generally, the equivalent R of RF circuit is 50 Ω. Taking LoRa signals working on 433 MHz frequency band (with 500 KHz bandwidth) as an example, this requires C to be as low as $5.2 \times 10^{-14} pF$.

Graham: Synchronizing Clocks by
Leveraging Local Clock Properties

Ali Najafi
Meta[†]

Michael Wei
VMware Research

[†]*Work done while at VMware*

Abstract

High performance, strongly consistent applications are beginning to require scalable sub-microsecond clock synchronization. State-of-the-art clock synchronization focuses on improving accuracy or frequency of synchronization, ignoring the properties of the local clock: lost of connectivity to the remote clock means synchronization failure.

Our system, Graham, leverages the fact that the local clock still keeps time even when connectivity is lost and builds a failure model using the characteristics of the local clock and the desired synchronization accuracy. Graham characterizes the local clock using commodity sensors present in nearly every server and leverages this data to further improve clock accuracy, increasing the tolerance of Graham to failures. Graham reduces the clock drift of a commodity server by up to 2000×, reducing the maximum assumed drift in most situations from 200ppm to 100ppb.

1 Introduction

The ever increasing performance demands of strongly consistent distributed applications has driven a desire for tightly synchronized clocks. Instead of communicating over the network, servers can establish an order over messages using a timestamp from a local clock [7, 18, 30]. Leveraging synchronized clocks has become more pervasive as applications require tighter latencies that approach the latency of the network itself. However, deploying finely synchronized clocks at scale remains a significant challenge, often requiring the use of specialized hardware [20, 22],.

In an ideal system, synchronizing clocks would be a trivial task. Clocks would never *drift* (lose or gain time) and a synchronized clock would stay synchronized forever. In real systems, however, clocks drift, so synchronization needs to be done frequently to keep clocks in time. Spanner [7], for example, assumes 200ppm drift, which translates into 200μs/s, a second roughly every hour, or a minute every 4 days. This drift increases clock uncertainty (ε) and limits the performance of

applications leveraging clocks, which must wait out the uncertainty. State-of-the-art systems today assume high clock drift and focus on increasing synchronization precision and frequency, with specialized hardware performing as many as 10K synchronizations per second to achieve sub-microsecond clock synchronization [17, 20, 22, 28]. Furthermore, systems assume missed synchronizations result in loss of synchronization, resulting in potentially unnecessary shutdowns due to clock uncertainty exceeding application requirements [20].

The clocks which drive the processor and timestamping hardware, however, are required to drift far less than these systems expect: datasheets from several vendors specify a clock crystal with at least ±20ppm temperature stability [9, 26]. An unstable clock could cause the system to violate the tight timing requirements required by the processor, memory and I/O subsystem. Local clocks can be much more stable than most systems assume. If we know that a system has lower drift, we can reduce the rate of synchronization, tolerate synchornization failures, reduce network congestion and the overhead of processing synchronization messages, as well as avoid the use of specialized hardware [4].

In this paper, we describe Graham[1], a system which models the stability of the local clock to determine the required synchronization rate. Graham leverages sensors available in every commodity server to characterize the clock against an accurate reference clock, such as GPS, PTP or even NTP. Graham uses this characterization to build a synchronization model, which determines how frequently the system must be synchronized and how many synchronization failures can be tolerated, and can achieve below 1ppm drift. In the servers we tested, we were able to achieve 100ppb stability in most cases, which is over 2000× better than the max drift rate assumed by Spanner. The guiding principle behind Graham is to improve the clock in software without adding additional hardware. This approach is challenging because existing sensors are not designed to characterize clocks, and are located at varying

---

[1]Named after George Graham (1673–1751), a clockmaker who improved the pendulum clock's accuracy by compensating for changes in pendulum length due to temperature.

distances away from the oscillators that drive system clocks. To address this challenge, Graham characterizes the system by observing the effect of temperature fluctuations at various sensors on clock error between synchronizations.

The contributions of this paper are:

- We debunk the myth that commodity computers have unstable clocks.

- We describe how to automatically characterize computer clocks using commodity sensors.

- We show that this characterization can be used to greatly reduce synchronization rates, resulting in 100ppb stability without specialized hardware.

2 Clock Generation and Synchronization

The term *clock* is often used for several related concepts. In this paper, we will use *clock* to mean a counter which is incremented at some frequency and can be used to measure time. Clocks are driven by *clock signals*, which oscillate between low and high logical states. A clock driven by this signal increments on a *clock edge*, which is the transition between two logical states (typically, the rising edge is used). Clock signals are provided by *clock sources*, which are typically quartz crystal oscillators in modern computers. In this section, we provide background on how clocks are generated and synchronized in a typical computer system.

2.1 A typical Linux Intel x86 clock system

Clock systems are architecture and vendor dependent, so we focus on a typical Intel Linux x86 machine as a model clock system. An Intel x86 system consists of multiple clocks which are driven by multiple clock sources. Some of the clocks accessible to users include the timestamp counter (TSC), real-time clock (RTC) and the precision time protocol clock (PTP). Each of these clocks run at different frequencies and serves different purposes, and which clock software ultimately can access has been shown to vary [23].

For the purposes of this paper, we center on the TSC, the clock typically accessed by applications via `clock_gettime(2)`. This clock is driven by a clock signal known as BCLK (typically 100MHz). The BCLK is driven by a phase-locked loop (PLL) which multiplies the frequency of a quartz crystal (48MHz on C620 ICC [9]). The BCLK is an important signal which not only drives the logic in the processor, but the memory controller and other components, depending on the processor model. Adjusting the BCLK is often done when overclocking by changing PLL parameters, but large adjustments can result in system instability and lockup.

So far, we have described how Linux enables applications to read a clock. In order to be able to compare one clock to another, clocks must be synchronized. Most Linux distributions rely on `ntpd` [24] or `chrony` [5] to synchronize local clocks to a remote server with a reference clock synchronized to wall clock time (UTC) via a time source such as GPS using the NTP protocol. The NTP protocol estimates the network delay between the server to client by dividing the round-trip delay in half and can achieve on the order of 1ms-100ms time synchronization error, with error increasing as the delay becomes more asymmetrical. In addition, since NTP is run in software, synchronization is subject to software jitter such as scheduling and interrupt handling which prevents NTP accuracy below 0.5ms, even in ideal conditions.

To achieve sub-microsecond accuracy, PTP (IEEE 1588) reduces software jitter [10]. First, instead of acting as a service where clients request the time, a PTP server continuously broadcasts the current time at periodic intervals. Clients estimate the network delay by sending a special message to the server to compute the round trip time and dividing that time in half. Finally, PTP introduces a new hardware clock located on the network card itself. This clock is driven by a different quartz crystal at the network card, usually corresponding to the frequency needed to drive the card's transceivers (25MHz for 10Gb Ethernet). The network card can capture the synchronization packets as they arrive to synchronize the PTP clock to the server, eliminating the inaccuracy introduced by software jitter. In Linux, `phc2sys` synchronizes the TSC clock to the PTP clock.

The accuracy of PTP is dependent on accurate delay estimation. Recognizing this limitation, Huygens [14] and Tick Tock [6] use coded probes and support vector machines to filter out queued packets from round trip delay estimation. Some commercial PTP implementations use packet delay variation (PDV) filters [27], and compensate for known latencies in the receive and transmit paths.

Because of clock drift, synchronization frequency is also important. While most of the latency sensitive paths of PTP are in hardware, it is still software driven, limiting the frequency of PTP synchronization, especially when filters are used that necessarily discard some synchronization data. This can be problematic if clock synchronization requirements are tight and clock drift is high. For instance, Huygens has a default sync interval of 2 seconds. A clock with 200ppm (0.02%) of drift will accumulate up to $400\mu s$ of drift between missed synchronizations. If there is a single transient synchronization failure resulting in a 4 second interval, up to $800\mu s$ of drift would accumulate, which would be problematic if an application required sub-microsecond clock accuracy. To increase synchronization frequency, most solutions require specialized hardware. For example, DTP modifies the Ethernet physical layer to exchange messages at the frequency of microseconds while reducing network delay nondeterminism [17]. Sundial leverages specialized hardware that synchronizes every $100\mu s$ and performs fast failure detection to notify software to recover by finding a backup clock [20].

2.2 Holdover Time

Notably, current state-of-the-art systems do not attempt to characterize the *holdover time* of the clock, which refers to the amount of time a clock can remain accurate without a synchronization. For instance, Spanner and Sundial both assume a static 200ppm maximum drift. If the maximum time uncertainty bound (ε) is 1μs, then a clock with 200ppm drift (200μs/s) will only be able to holdover the clock for 5ms without synchronization before *potentially* exceeding ε. The formula for holdover time can be given as:

$$t_h = \frac{\varepsilon}{\mathrm{d}f} \qquad (1)$$

Where t_h is the holdover time, ε is the maximum time uncertainty, and $\mathrm{d}f$ is the clock drift. 200ppm, however, is very conservative: most quartz crystals used for computer systems are specified on the order of 100ppm of error, and only when operated under extreme operating conditions. In the next section, we describe how we can characterize oscillator error, and use this characterization to increase the holdover time.

2.3 Characterizing Oscillator Error

Oscillators provide the clock signals that ultimately drive the clocks used in computer systems, and are the source of most clock error. The most common oscillator in use in nearly all computers today is a quartz crystal, which uses the pizeoelectric properties of quartz to produce a clock signal at a given frequency.

Quartz is cut to resonate at a given frequency, however, as the cut is a mechanical process, tolerances in the cut process may result in a resonant frequency which is slightly offset from the advertised frequency, known as the frequency tolerance. Since any error in the cut is usually fixed, this tolerance results in a fixed offset from the advertised frequency. In typical computer crystals, this error is usually in the 50ppm range. Lower tolerances require more accurate (e.g., fine laser) cuts and are significantly more expensive.

Quartz crystals also age over time as mechanical devices which are constantly vibrating, slowly deviating from their advertised frequency. This error is usually small (5ppm/year) [1], and also results in a slight frequency offset.

So far, we have described sources of quartz crystal oscillator error which are relatively constant. As physical devices, the frequency of quartz crystals are also affected by environmental changes. The most prominent factor is temperature [36], which can result in a significant change in frequency over the crystal's operating temperature range. While temperature can induce variations in the frequency of the crystal, the temperature-frequency response of crystals are quite deterministic: in fact, some crystal manufacturers produce the response curve on the crystal datasheet. Typical crystals produce anywhere from a 30ppm-100ppm change in frequency over their operating temperature ranges [1].

Table 1: Frequency Error in Standard Quartz Oscillators

Name	Typical Range	Typical
Tolerance	$\pm$50 ppm	-
Aging	$\pm$5 ppm/year	-
Temperature	$\pm$1 ppm/$^\circ$C	$\pm$15 ppm (25-40°C)
Voltage	$\pm$1 ppm/V	$\pm$0.1 ppm ($\pm$2% 3.3V)
Load	$\pm$0.1 ppm/pF	$\pm$0.1 ppm ($\pm$10% 15pF)
Acceleration	0.1 ppb/G	0 @ Rest
Time Dilation	0.1 ppq/m	0 @ Sea Level

In addition to temperature, a variety of other environmental factors will affect the frequency of the oscillator. However, these factors contribute a relatively small amount of frequency error compared to temperature. Changes in supply voltage usually result in a 0.1ppm-5ppb change in frequency. Another factor is variation in the load capacitance: in order for the crystal to resonate at the expected frequency, the correct amount of capacitance is required. Since the capacitors used to provide the load capacitance also have tolerances, the capacitance can vary depending on the properties of the capacitors used. Typically, load capacitance error is specified at 0.1ppm-5ppb [29, 33]. The frequency of quartz crystals are also sensitive to acceleration, depending on the axis it is applied to. For ordinary quartz crystals, this is typically in the range of 0.1-10ppb/G [29, 33]. For a 500G shock, such as that specified in MIL-STD-883H, representative of a device dropping to the floor, frequency error could be as high as 1ppm [19, 33]. Note that the recommendation for operational vibration and shock limits in datacenters is less than 5G [16] which is well below 500G. Finally, crystals are even sensitive to relativity: a crystal closer to the gravitational field of the earth will have a lower frequency than a crystal further away, such as on a mountain or in space. This error is around 0.1ppq/m from sea level, or ≈ 0.9ppt at the top of Mount Everest or ≈ 3ppb from geostationary orbit [33].

These sources of error are a result of the physical properties of quartz, and the data collected in Table 1 are collected from the datasheets of various quartz oscillators used in servers [1, 19, 29, 33, 36].

2.4 Debunking the Myth of Unstable Clocks

As we have seen, most of the frequency error in a quartz oscillator is either relatively static or dependent on temperature. Voltage and load only contribute a small amount of error and should be within small tolerances (otherwise, other parts of the system may begin failing). Servers in most datacenters are stationary, so the effects of acceleration and time dilation should be constant.

Static error can be easily corrected if it can be learned: if we learn that our crystal resonates at 32.769 KHz instead of 32.768 KHz, we simply need to adjust our accounting of time,

perhaps by using 32769 as a divider instead of 2^{15}. If our synchronization error is minimal and we keep the temperature constant, we can learn this value over several synchronization passes. NTPd and chrony both try to learn the static drift using the *driftfile*.

Most state-of-the-art systems, however, combine static and dynamic error in their uncertainty calculations, resulting in the assumption of an unstable clock. For instance, Sundial assumes that the clock error of their oscillator is 100ppm, but this number includes the static tolerance error from the cut, which is easily learned. Moreover, even if they had chosen a ±100ppm temperature tolerance crystal, this shift would be over the entire operating range, as in a shift from -30°C to 85°C. An overheating server moving from 60°C to 80°C would experience only about 20ppm change in drift from temperature, an order of magnitude less than the conservative 200ppm error used in spanner.

In practice, most crystals used to generate processor clocks have temperature tolerances in the range of ±20ppm. Intel Chipset Integrated Clock Controllers (ICC), for example, specify "Total of crystal cut accuracy, frequency variations due to temperature, parasitics, load capacitance variations is recommended to be less than 90ppm" [9], and external clock generators such as the common CK420BQ used in Intel systems specify a cut tolerance of ±20ppm and a temperature tolerance of ±20ppm over the entire operating range [26]. If we can filter out the static error, we will be left with 20ppm temperature error. Then this clock will have a 1 μs holdover time of 50ms, a 10× improvement over the 200ppm assumption.

2.5 Software Temperature Compensation

Once we have corrected the static frequency error, temperature remains as the dominant source of frequency error. This effect is well known, and software compensation techniques are described in the literature [13, 15, 25]. In computers, chrony can correct for temperature errors given the temperature-frequency relationship and a temperature sensor. In wireless networks, where minimizing clock error is critical, environment and temperature aware compensation are used [34, 35].

While temperature-frequency curves are sometimes published on the datasheet of a crystal, using them to correct errors on a commodity computer system requires knowing the crystal used. This can be difficult even for an expert given the small markings on most crystal packages. Moreover, the crystal used can be different even across the same model of motherboards, since manufacturers may substitute functionally equivalent parts due to cost or supply-chain reasons. Unless the system was purpose built with temperature correction in mind, temperature sensors are likely located some distance away from the crystal. Therefore, selecting the right temperature sensor may be a challenge. However, correcting for temperature error can effectively reduce the frequency

error of the crystal to less than 1ppm, resulting in a 1 μs holdover time of 1s, a 200 × improvement over Spanner's assumption.

2.6 Other Oscillators

Many applications outside of general-purpose computing, such as wireless require low frequency error over a wide temperature range. The temperature compensated crystal oscillator (TCXO) consists of quartz crystal with a temperature compensation circuit and reduces the effect of temperature to ≈ ±1ppm of error. The oven compensated crystal oscillator (OCXO) takes temperature control one step further and places the crystal in a miniature oven which keeps the crystal at a constant temperature, reducing temperature effects to ≈ ±1ppb. This oven can be doubled (DOCXO) to achieve ≈ ±0.1ppb of temperature error. Atomic oscillators, which work based on electron transitions, can provide even more stability: rubidium oscillators provide up to 0.0002ppb/s. The cost of these oscillators is often cited as prohibitive, but can be quite inexpensive, relative to specialized hardware. For instance a 48MHz TCXO at 0.5ppm suitable for driving an Intel ICC costs around USD $2 [11], and a 25MHz OCXO at 10ppb suitable for driving a CK420BQ clock synthesizer costs around USD $70 [2].

While replacing the oscillators in computer systems might be an option in new, future hardware, it is an invasive and expensive procedure for existing hardware. The focus of Graham is to democratize accurate clocks using only existing hardware. Using software techniques, we can achieve low error without adding additional hardware.

3 Clocks and Sensors In Servers

In order to understand how temperature sensors can be used to estimate clock error in commodity systems, we studied the sensor and time configuration of a variety of platforms. One unexpected challenge was the difficulty of accurately measuring clock error.

Clocks. The Linux pulse-per-second (PPS) [21] facility provides a mechanism for delivering an accurate reference time. PPS devices are devices that accurately emit a low-jitter pulse every second. A PPS driver calls the `pps_event` API whenever the pulse is received, and the kernel records the timestamp associated with that pulse. Typically, this pulse is a signal that causes an interrupt, and the PPS API is called by an interrupt service routine (ISR). However, even when using very low jitter PPS devices, such as the ublox ZED-F9T [32] GPS timing module that advertises ±4 ns jitter, we saw jitter over 10μs. As we diagnosed the problem, we saw several sources of jitter throughout the hardware and software stack which made it difficult for our driver to call `pps_event` in a timely manner after the pulse interrupt is raised.

Our initial approach was to use GPS dongles with PPS support over USB[2], which are inexpensive (USD ≈$10), readily available, and usable on nearly every server. The GPS device presents itself as a serial device, and the PPS interrupt is encapsulated as a message over the USB bus. We saw that the polling message-driven nature of USB resulted in high jitter: not only was there a ≈100μs delay (which is easily corrected for), but also ±10μs of jitter that made it difficult to accurately time the pulse. Our next attempt involved using a FPGA to deliver an interrupt over PCIe, since PCIe slots are readily available in most commodity servers. However, while PCIe offered less jitter PCIe interrupts are also message signaled and also saw as much as ±5μs of jitter dependent on device traffic and serial transceiver jitter.

We needed a low-latency interrupt pin to accurately capture the PPS signal. We ended up resorting to using the legacy serial port, which exposes interrupts pins on the device carrier detect (DCD) and clear to send (CTS) lines. Unlike PCIe and USB, these legacy ports drive an interrupt pin on the low-pin count (LPC) bus and offer much lower jitter, on the order of 1μs. Even with the serial port, we still saw significant "blips" in our PPS signal. To reduce those blips, we made several changes: first, we pinned the serial port interrupt to a single core, disabled power management, disabled all watchdogs, installed a "lowlatency" kernel, turned on interrupt threading and set the serial interrupt priority to realtime. While these changes reduced the number of blips, there was still periodic noise present which made time daemons such as chrony detect as much as 10ppm of drift change over a second. This drift only disappeared when we forced the C-state of the machine to C0, disabling idling. This surprised us: the CPU advertised `FEATURE_NONSTOP_TSC`, so the TSC should not be affected by C-States. We realized that the most likely scenario was that when idling was enabled, the CPU would take a non-deterministic amount of time to wake up from sleep and fire the ISR that eventually causes `pps_event` to be recorded.

To deal with this scenario, we took advantage of the two time pulse outputs of the ZED-F9T module and connected the second time pulse to the CTS serial line. We configured the second time pulse with a 400ns delay from the first one, and modified the kernel PPS serial line discipline driver to only record the second pulse if is 400ns ± 100ns from the first pulse. While this caused some pulses to disappear, it greatly reduced the jitter we observed. To compensate for lost time pulses, we changed the time pulse frequency from 1Hz to 3Hz. Removing this software jitter enabled us to see that the clock was actually fairly stable over long periods of time, only deviating by about .5ppm per hour, as seen in Figure 1. We suspected most of this deviation was due to the rising ambient temperature.

[2]To expose the PPS signal, we used a common FT232H USB-to-RS232 converter and connected the PPS line to the DCD signal expected by the PPS serial line discipline driver.
(a) Frequency Error Without Dual Time Pulse, all C-states enabled.

Table 2: Systems Evaluated and Temperature Sensors

Name	Type	Crystal Location	Sensors
Server	2S 1U Rack	Near Chipset	50
Workstation	Desktop	Chipset	8
Pi 4	SoC	Under SoC	1
Pi 3	SoC	Under SoC	1

Sensors. Modern computer systems are littered with sensors for environmental conditions. The original use of these sensors were to monitor alarm conditions: for example, to shut off the system if there are abnormally high temperatures that would cause instability, or if a voltage regulator malfunctions. A more recent use of temperature sensors is for thermal throttling, which reduces the frequency of a processor or GPU based on the temperature. The goal of Graham is to reuse these temperature sensors for the purpose of performing software-based temperature compensation.

Using these temperature sensors can be challenging because their location relative to the clock crystal is not consistent. While crystals are usually located near the clock generator, the clock generator can be located in a number of locations, which might not be at all near a temperature sensor. Systems also have a varying number of sensors, as shown in Table 2. The server platform we evaluated, for example,
Figure 2: **Server Platform Temperature Map.** The server platform contains over 50 sensors with approximate positions labeled.

Figure 3: **Temperatures and Polynomial Fit.** Even though there is variation in the measured delay, a polynomial fit curve can still be plotted against it.

has nearly 50 sensors (Figure 2). However, even though the platform provides the position of these sensors, it is still of little help to determine which sensor is closest to the crystal. As an additional challenge, not all temperatures offer the same precision. For instance, some of the sensors in the server platform only reported $\pm 10°C$ changes, likely because they were designed only for use as an alarm. Finally, the response time of the sensors may vary depending on various environmental factors. For instance, a sensor located near the large copper ground plane of the motherboard may respond slower to rising temperatures than a sensor located on a the thinner PCB of a DIMM. An ideal sensor has high precision and responds quickly to changes in the same way as the crystal.

Establishing the Ground Truth. Armed with an accurate timing signal and a number of candidate sensors, our next goal is to attempt to establish the "ground truth", or the temperature-clock error response curve. If we can determine the clock error given a certain temperature, then we can correct the clock even in the absence of the accurate timing signal.

Nearly all quartz crystals used in computers today are AT-cut crystals. Their frequency relationship with temperature can be described by a 3rd order equation [3, 8, 12, 36]:

$$\Delta f_T = k_0 + k_1 T + k_2 T^2 + k_3 T^3 \qquad (2)$$

where Δf_T is the crystal frequency error due to temperature, T is the crystal temperature and k_i are coefficients of the frequency versus temperature curve. To find the relationship of the clock frequency versus temperature we need to solve for the k_i parameters using synchronization messages from a reference clock. Unfortunately, since the sensor data is noisy, we may need to obtain many temperature points to "average out" the sensor error. This required designing an experiment which required many passes, and was difficult to perform on a server platform. As a result, we performed most of our ground truth tests on the Raspberry Pi (Pi 3/Pi 4) SoC systems, though we

show our full implementation of Graham in action on desktop and server platforms in Section 5. While the Raspberry Pi is an ARM-based SoC, it runs Linux like the x86 system and has a clock driven by a quartz crystal on the underside of the SoC PCB.

The Pi, as a bare SoC system, allowed us to easily subject it to various temperatures. The Pi includes a temperature monitor which measures the core SoC temperature. We provided an accurate PPS timing pulse using a uBlox Neo-M8N GPS module [31] to a Pi GPIO and exposed it to various temperatures using either a hair dryer or ice bucket. We used the difference in timing ticks between PPS signals to calculate the estimated frequency error of the crystal, and the result is plotted in Figure 3. The distribution we saw was around ± 5 ppm and probably attributable to interrupt delay and sensor error.

Once we saw that we were able to capture the temperature-error relationship, we wanted to ensure that the data we were generating was repeatable, so we collected several traces using varying temperature patterns, all exercising the same temperature range. Figure 4 shows that the curve we generated was similar even with different temperature inputs.

Next, we wanted to see if the curves differed across devices. Figure 5 shows that even across devices of the same model, curves are significantly different. Even the same crystal model could be cut slightly differently, resulting in two 25MHz crystals which are for example, 24.997MHz and 25.001MHz that meet the tolerance requirement, but yield different curves.

Finally, because age can have an effect on the crystals, we wanted to test if we could observe a change in the curve with age. In Figure 6, we ran two tests with a 7 month time difference, obtaining two slightly different curves, as expected. The 1ppm offset we obtained roughly matches the aging expected by a regular quartz crystal during this time period.

Now that we have obtained the ground truth using an accu-

Figure 4: **Repeatability of the Curve.** We measured several traces using different temperature patterns (Test 1-5) by varying the use of ice and the hair dryer and we obtained similar temperature curves.

rate PPS signal, we use this knowledge to guide us in scaling our solution to many devices. Since each device will have its own unique curve, it became clear to us that we needed to design a way to automatically learn the curve of each device.

4 Graham Design

The overall approach of Graham is to learn the temperature-clock error relationship by fitting curves as new data points are learned. Unlike the experiments we designed when trying to learn the ground truth, we cannot expect to be able to point a hair dryer or dump a production server in ice. In addition, since a truly scalable solution should not require a precise PPS timing signal, we need to ensure that we can perform this learning with traditional synchronization protocols such as NTP or PTP. As a result, Graham must fit these curves over time on incomplete and noisy data. Once we determine that the we have observed enough data points, we can use the derived curve to correct the time error. To fit this data on a curve, we begin by formalizing the variables and equations required to solve for the time error.

4.1 Formulating the problem

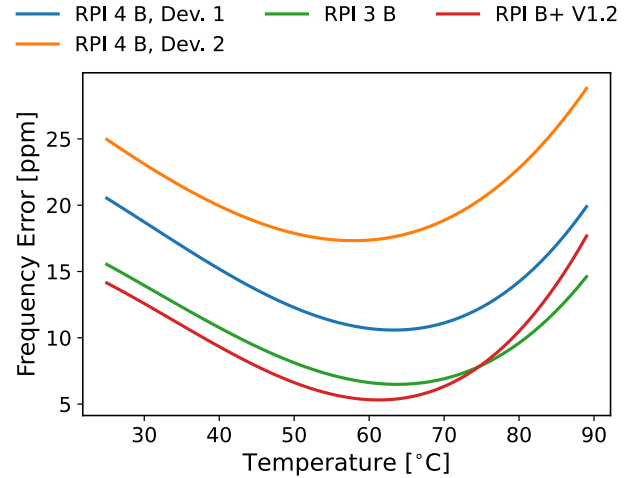
We previously described the relationship of the crystal error with temperature as a cubic polynomial in Equation 2. However, we cannot directly measure the frequency of the crystal to obtain the error. Instead, we can obtain two timestamps from the clock using a known time interval and calculate the difference to see how much it deviates from the expected difference.


Figure 5: **Curves Across Devices.** We observed that different devices, even of the same model had varying curves.
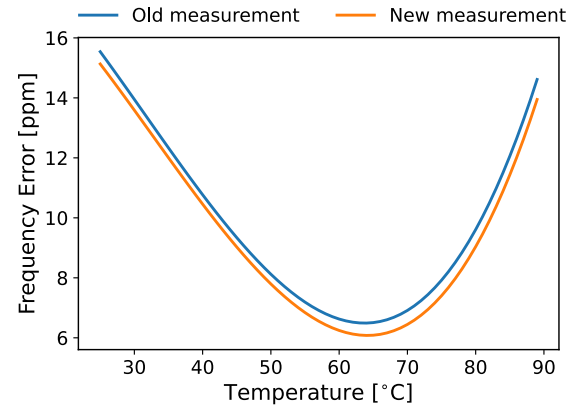

Figure 6: **Aging of Devices.** As a device ages, the curve can change due to crystal aging effects.

For example, a clock crystal may have an ideal frequency (f_0) of 32.768KHz. We would expect two timestamps taken exactly 1 second apart to have a difference of 1 (Δts_i). But if we actually observe 1.5 seconds (Δts_o), then we know the actual frequency is 49.152KHz (f_1), or $1.5 \times f_0$. If we subtract the two frequencies, we obtain 16.384KHz of frequency error (Δf). We can express this as an equation:

$$\Delta f \Delta ts_i = \Delta ts_o - \Delta ts_i \tag{3}$$

in which Δf is the relative frequency error. If we assume most of the frequency error is from temperature, we can replace Δf_T in Equation 2 with Δf. Then we obtain:

$$(k_0 + k_1 T + k_2 T^2 + k_3 T^3)\Delta ts_i = \Delta ts_o - \Delta ts_i \tag{4}$$

Eq. 4 is a linear equation with 4 unknowns – k_0, k_1, k_2 and k_3. Timestamp interval Δts_o can be obtained from the

system's local clock and the timestamp interval Δts_i can be obtained from synchronization messages. If we receive N synchronization messages then we can build N linear equations as follows:

$$AK = B \qquad (5)$$

in which A, K and B are matrices equal to:

$$K = \begin{bmatrix} k_0 \\ k_1 \\ k_2 \\ k_3 \end{bmatrix}, \quad A = \begin{bmatrix} 1 & T_1 & T_1^2 & T_1^3 \\ 1 & T_2 & T_2^2 & T_2^3 \\ \dots & \dots & \dots & \dots \\ 1 & T_N & T_N^2 & T_N^3 \end{bmatrix} \qquad (6)$$

$$B = \begin{bmatrix} \Delta ts_{o,1} - \Delta ts_{i,1} \\ \Delta ts_{o,2} - \Delta ts_{i,2} \\ \dots \\ \Delta ts_{o,N} - \Delta t_{i,N} \end{bmatrix} \qquad (7)$$

in which T_N, $\Delta ts_{i,N}$ and $\Delta t_{o,N}$ are respective parameters for the Nth synchronization message and equation. Graham solves Eq. 5 using linear least square methods.

So far, we assumed that the temperature is constant for the duration of Δts_o. If the synchronization messages are infrequent, as in the case of a protocol such as NTP, the temperature can change during this period. To solve this problem, Graham records temperatures during this period and when it receives a synchronization message, it aggregates the effects of temperatures. Assume there are n intervals in which we record temperatures during a period. The equation for the jth time interval is:

$$\Delta f_j \Delta ts_{i,j} = \Delta t_{o,j} - \Delta t_{i,j} \qquad (8)$$

$$\Delta t_o = \sum_j^n \Delta t_{o,j} \qquad (9)$$

$$\Delta t_i = \sum_j^n \Delta t_{i,j} \qquad (10)$$

$$\sum_j^n \Delta f_j \Delta t_{i,j} = \sum_j^n \Delta t_{o,j} - \sum_j^n \Delta t_{i,j} \qquad (11)$$

Using Eq. 2, 9 and 10, we get:

$$k_0 \sum_j^n \Delta ts_{i,j} + k_1 \sum_j^n T_j \Delta ts_{i,j} + k_2 \sum_j^n T_j^2 \Delta ts_{i,j} \\ + k_3 \sum_j^n T_j^3 \Delta ts_{i,j} = \Delta ts_o - \Delta ts_i \qquad (12)$$

where T_j is the temperature at the jth time interval. Note that, $\Delta ts_{i,j}$ is an unknown parameter. We can be approximated it by $\alpha \Delta ts_{o,j}$ in which $\alpha = \frac{\Delta t_i}{\Delta t_o}$.

$$k_0 \sum_j^n \Delta ts_{o,j} + k_1 \sum_j^n T_j \Delta ts_{o,j} \\ + k_2 \sum_j^n T_j^2 \Delta ts_{o,j} + k_3 \sum_j^n T_j^3 \Delta ts_{o,j} = \\ \frac{\Delta ts_o - \Delta ts_i}{\alpha} \qquad (13)$$

Similar to Eq. 4, Eq. 13 is a linear equation with 4 unknowns and we can solve it using similar linear least square methods.

4.2 Implementation

We implemented a prototype daemon in C which solves for the equations by using temperature sensors exposed through sysfs or a network management interface such as SNMP. We record temperatures with $1°C$ precision at a configurable frequency, which defaults to 1Hz. For synchronization data, we modified chrony to collect the Δts_o and Δts_i necessary from synchronization messages over NTP.

Graham keeps a FIFO queue of equations with known size for each temperature, bounding the number of equations that need to be solved. Graham assumes an operating temperature range of 40-80°C and does not start applying corrections until the curve errors are within 20ppm. Graham constantly collects temperature data to learn the curve before corrections are applied.

4.3 Addressing practical issues

In 4.1, we assumed an ideal case in which all the known parameters to solve for the clock frequency versus temperature are accurate. However, that is not the case in practical systems. We outline these inaccuracies and non-idealities and explain how we can address them.

4.3.1 Timestamp Error

There are two main sources of timing error in the system:

Error in $\Delta t_{o,i}$. Since the temperature changes happen in the timescale of seconds, even several milliseconds error in the observed $\Delta t_{o,i}$ values will have a limited effect on the result.

Error in $(\Delta t_i - \Delta t_o)$. This value is the combination of 3 parameters: crystal frequency error (Δf), jitter in timestamps and network asymmetry from the time server to our system. Graham is interested in only Δf, but the last two parameters are error (δt_{err}) and add noise to our measurements.

$$\Delta t_o - \Delta t_i = \Delta f \Delta t_i + \delta t_{err} \qquad (14)$$

Note that δt_{err} is only dependent on the type of timestamping (software and hardware) and the method of the synchronization (NTP, PTP, PPS and ...). The error in curve estimation

is determined by $\frac{\delta t_{err}}{\Delta t_i}$. Therefore, as we increase Δt_i, the first term in Eq. 14 increases while the second term is constant and we can increase the curve estimation accuracy. Moreover, δt_{err} can be modeled as a random variable with zero mean. As we increase the number of equations, we can average out the δt_{err} and in turn the lower the estimation error. By having a high enough number of equations and building equations for longer durations we can increase the curve estimation accuracy.

4.3.2 Temperature Sensor Challenges

Leveraging already existing temperature sensors requires addressing several challenges:

Accuracy. Temperature sensor accuracy has limited effect on correction performance since both learning the relationship of the clock frequency versus temperature and applying the correction is done using the same temperature sensor.

Precision. Low precision means that temperature measurement readings have a random variability. Having a higher number of equations will average out these random errors. This means that as the temperature sensor's statistical measurement variance increase we need higher number of equations.

Responsiveness. A temperature sensor which does not respond to temperature in the same way the crystal does will limit the effectiveness and potentially contribute to error. This responsiveness of a sensor can be measured by checking the temperature error curve. In a system with multiple temperature-error curves, we select the sensor which minimizes the frequency error during learning runs.

4.3.3 Computation Accuracy

The computed curve is only accurate for the temperature ranges that the system has experienced. For example, if Graham only has equations for temperatures from $50°C$ to $80°C$, the curve is accurate in that range and close to boundaries of that range. As we go far from this boundary the accuracy of the curve decreases. One of the main reasons for this is that the temperature-error curve is cubic, but the typical operating range of the server is only within a small convex region of the curve. Two of the roots are likely at the extreme temperature ranges, and one root is likely in the extreme negative (below freezing region).

To exercise a variety of temperature ranges without using a heater or ice, we load the CPU and allow the system to cool off.

5 Evaluation

Our evaluation of Graham is motivated by the following:

- How effective is learning over a noisy synchronization channel such as NTP? (§5.2)

(a) After 40 Eq ($\approx$12h) (b) After 80 Eq ($\approx$24h)

(c) After 120 Eq ($\approx$36h) (d) After 160 Eq ($\approx$48h)

Figure 7: **NTP Learning.** While learning over NTP takes longer, the curve converges towards the same curve produced by faster, more accurate synchronization sources.

- What is the holdover time Graham can achieve, and how many synchronization failures can it tolerate? (§5.3)

- Can Graham compensate for rapid changes in temperature, as in with a HVAC failure?(§5.4)

Test Platforms. The primary system requirement to be able to apply Grahamis the presence of a temperature sensor which is present in nearly all modern computer systems. We evaluated Graham on several platforms, as shown in Table 2. For the Pi tests, we used a ublox M8N [31] GPS receiver with a time pulse accuracy of $\pm$60ns (99%). The M8N module does not specify jitter, but we observed $\pm$20ns jitter using a RIGOL MSO5074 oscilloscope. For the x86-based platforms, we used a ublox ZED-F9T [32] GPS module which specifies a time pulse accuracy of $\pm$5ns (1σ), and a jitter of $\pm$4ns. In our tests, we are mainly concerned about jitter, as the timing accuracy specifies the accuracy of the timing pulse to GPS time, and these GPS modules have their own TCXO oscillator.

5.1 Learning over PPS

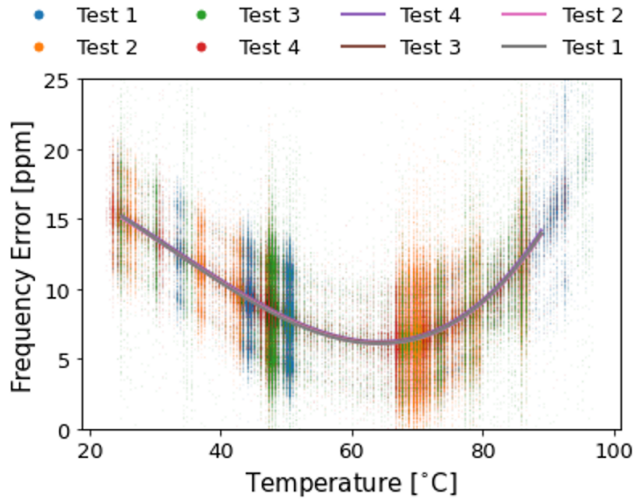
We obtained baseline curves with Graham using PPS. With PPS, we generate 1 new equation per second, corresponding to the frequency of the synchronization signal. As shown in Figure 8, even though the temperature data we used to generate each curve was quite different, the curves are almost the same. While the curves look similar, the constants for each curve varies. This is because there are many cubic equations which can fit the small convex portion of the curve that we observe within the operating temperature range.


Figure 8: **PPS Curves and Input Data.** Curves learned over each experiment have a similar shape despite having variable input data.

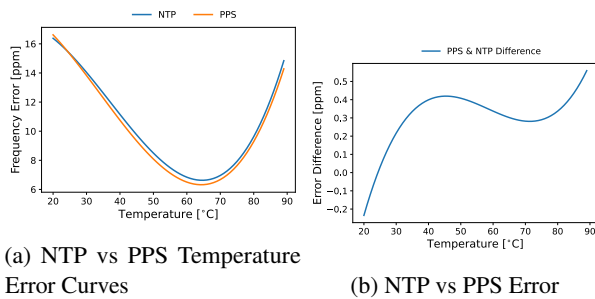


(a) NTP vs PPS Temperature Error Curves

(b) NTP vs PPS Error

Figure 9: **NTP Performance Compared to PPS.** The learned curves for NTP are within 0.5ppm of the PPS curves for most of the operating range.

5.2 Learning over NTP

To evaluate learning over NTP, we used chrony to obtain NTP synchronization data for Graham against public NTP servers over a standard home cable broadband connection, with a ping latency to the NTP server between 30–40ms. This resulted in synchronization accuracy in the ms range. In order to compensate for this, we needed to use high $\Delta t s_o$. For NTP, we use $\Delta t s_o$ = 1000s, which results in one equation every 1000s as opposed to 1 equation per second with PPS. Note that $\Delta t s_o$ is independent of the synchronization periods and intervals used by chrony, which has its own algorithm for NTP synchronization frequency.

Figure 7 shows the 160 equations we collected over the course of a 48 hour run. This resulted in a curve within ±0.5ppm of the curve generated using PPS signals, as shown in Figure 9. We suspect that the error of the curve is not constant because of lack of data points at temperature extremes

for both sets of data.

5.3 Holdover

Once we have learned the temperature-error relationship, we wanted to evaluate how well Graham's time frequency correction would perform in the absence of synchronization messages. To test the accuracy of the frequency correction, we recorded the accurate PPS time pulse, but did not provide it to Graham. We measured the accuracy of Graham's time correction versus the real time. We then exposed the system to a new temperature trace.

Pi Experiments. Figure 10 shows a trace of one of these experiments on the Pi 3. In this particular experiment we exposed the system to both ambient air effects of the 8 hour time period as well as artificial cooling (ice) and heating (hair dryer). The red vertical line shows the rapid growth of time error if Graham did not perform any compensation. At 620s, this well exceeds $5000\mu s$ of drift, which corresponds to the the 8ppm of temperature drift Graham is trying to correct for. On the other hand, Graham's corrections perform very well, never exceeding $1500\mu s$ of error over the course of the entire 8 hour run, even though the temperature is shifting significantly. For most of the test, the slope never exceeds 100ns/s of error, which means the clock is performing as well as one with only 100ppb of error, a $200\times$ improvement over the performance of the 20ppm crystal, performing nearly as well as a high quality TCXO or some OCXOs. We can calculate the holdover time using the slope from Equation 15, given a maximum time uncertainty (ε). If ε=1μs, then the holdover time during the 100ns/s region is:

$$t_h = \frac{1\mu s}{100ns/s} \qquad (15)$$

or $t_h = 10s$. In other words, the corrected clock will not exceed 1 μs of error for at least 10 seconds *without* any additional synchronization. This would enable more infrequent synchronizations, or enable the system to tolerate the very real potential of missed synchronization messages. In one part of the graph, we experience a 330ns/s slope, when the temperature exceeds 85°C. We speculate that this slope is because the training temperature data we used had very few points at or above this temperature. 330ppb still is very good: we obtain a 1μs holdover time of 3 seconds, which still allows for lower frequency synchronizations.

Server Experiments. We also evaluated the holdover time on desktop and server x86 systems. These systems are much more complex and contain multiple sensors and fans, so Graham needs to determine which sensor works best, given a variety of factors. There are also multiple components which can generate heat load, which vary from system to system. Notably, the many fans in the server made it more difficult to
(a) Time drift

(b) Temperature

Figure 10: **Holdover.** The uncompensated temperature drift quickly increases while Graham is able to maintain the time with minimal drift. The slope of each part of the graph corresponds to the frequency error performance: $s_1 = 50$, $s_2 = 80$, $s_3 = 330$, $s_4 = 100$, $s_5 = 30$, $s_6 = 15$ ns/s.

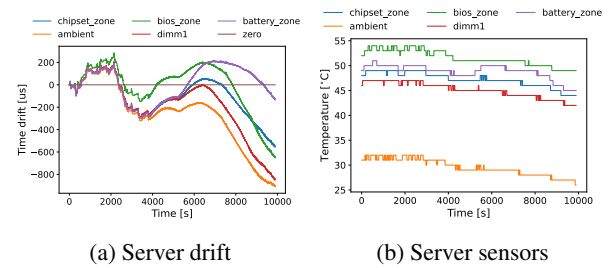
(a) Server drift

(b) Server sensors

Figure 11: **Warming Server Holdover.** With a server sitting in a garage on a hot summer day, Graham is able to maintain 0.1ppm of error.

create rapid changes in temperature. To get a picture of the server sensor's performance, we performed a 24 hour learning run exposing the server to various temperatures while heating it from the fan intake and letting it cool via ambient cooling, and running `stress-ng` in various modes to create load on the system. We then exposed the server to a new temperature curve.

Figure 11 shows the holdover graph for the server during one of our first tests, which is just ambient warming of the server in a garage on a hot summer day. We selected the 5 best performing sensors. Surprisingly, even though we thought the "chipset_zone sensor" would perform the best, "dimm1" actually produced the best correction curve. We wanted to ensure that this would be the case even in a loaded system, so we performed a memory test using `stress-ng` to see if heat from a memory load would affect our learned result. Figure 12 shows the holdover curves from that run, with the memory test running at time 0. The DIMM 1 sensor still remained one of the top performing sensors, producing less than 200μs of drift over the first 2000 seconds of the run, or 0.1ppm error. Many of the other sensors perform well too, likely because they experience similar patterns of temperature changes. The impact of the load, however, can be seen across Figure 11 and Figure 12: while the ambient temperature works well without a load, its performance is worse when a load is present. In all our runs with the server workload, we never observed more



(a) Server drift

(b) Server sensors

Figure 12: **Memory Load Holdover.** The DIMM sensor remains the best sensor, even when the server is under memory load.

than a 0.2ppm error with Graham.

Desktop Experiments. Finally, we evaluated Graham on a typical desktop machine. Unlike the server, which is fully instrumented with sensors throughout, the desktop machine we used only had a few sensors exposed by default, just on the CPU die and the DIMMs. However, during our experiments, we made an error to include the output of the fan sensors (in RPM) as training data. Surprisingly, the fan sensors worked well even though they were not directly measuring the temperature. We suspect that the speed of the fan is driven by a combination of the ambient temperature, (which is not exposed to the user) and dynamic CPU load by the hardware monitor. However, we ended up using the second core sensor, which is located closer to the chipset and crystal. This gave us 0.1ppm error on nearly all experiments.

Figure 13 shows a peculiar experiment on the desktop platform where we failed to expose the server to all temperature points. In the first 2000 seconds we run a CPU load experiment, which resulted in the a higher than expected error (0.5ppm vs 0.1ppm). After debugging, we realized this was because the temperatures we exposed to Graham during testing (Figure 13c) were not learned (Figure 13d). In particular, the testing temperatures were above 70°C for the first 2000s, while the learning temperatures were below. Still, we thought this test showed that even without learning temperatures, Graham can provide some correction to the temperature error.

5.4 Rapid Changes

One of the often cited sources of timing instability in computer systems is a thermal shock event, such as an HVAC failure. To evaluate Graham's performance in dealing with a rapid thermal shock, we used the Pi system and pointed a hair dryer directly at it, attempting to raise the temperature rapidly to the maximum operating temperature. As with the holdover tests, we turned off synchronization and only relied on Graham's temperature-based frequency error correction.

Figure 14 shows the time drift after correction by Graham (left) which results from the rapidly rising slope in tem-

(b) Temperature

(c) Uncorrected

Figure 14: **Thermal shock.** Even with a hair dryer's rapid heat, Graham is able to quickly compensate for errors in time, never drifting beyond 10μs.

perature (right) from the hair dryer. Using the hairdryer, we were able to produce a 2°C/s slope, which cools at about 0.2°C/s. While we feel that such fast heating is unlikely to happen, it may be representative of an HVAC failure, and is an indication of the robustness of Graham's temperature correction: the time drift never exceeds more than 10μs over the initial 25 second slope, a drift of only -0.4ppm. Once the temperature slope decreases, Graham is able to maintain the time without exceeding the initial 10μs of error. Without Graham, the system accumulates nearly 1ms of error during this time period (bottom).

6 Discussion

Our evaluation has shown that Graham can maintain clock frequency error below 1ppm using commodity sensors in a variety of conditions. Graham is only one part of the solution, however – while Graham can maintain a long holdover time, the synchronization maintained will only be as good as the initial synchronization.

Graham works in synergy with other synchronization mechanisms, such as Huygens [14], PTP [10] and FaRMv2 [28] to maintain synchronization. Our experiments with NTP show that Graham can maintain 1μs ϵ for 10 seconds after loss of synchronization. As Sundial [20] shows, however, missed synchronizations can occur for a number of reasons. For Huygens, significant CPU load on the system could occur causing the SVM processing to be delayed, and in PTP and FaRMv2, synchronization messages could be missed, leading to increased uncertainty of time. Using our 1μs holdover result for Graham, we could reduce the standard 1s synchronization frequency of PTP to 3s and tolerate 2 lost synchornization messages.

Graham also aims to democratize precise time by enabling commodity servers, desktops and even SoCs to have access to stable clocks without adding specialized hardware. One of the barriers we see in adopting precise time for these devices is the myth of the unstable clock, which is perpetuated by the challenge of measuring the drift in the clock in the first place. Software noise can give the illusion that a clock is drifting rapidly, even though hardware clocks are relatively stable. Unfortunately, without specialized hardware, drift is measured by software itself, further exacerbating the problem. By characterizing the clock. Graham enables applications to trust the hardware instead of relying on noisy software measurements.

In the future, we may consider incorporating multiple sensors to the equations Graham solves for better accuracy. As more applications require precise time, we expect systems with TCXOs or OCXOs to come on the market, and expect that Graham performs favorably against them.

7 Conclusion

It has been long thought that computer clocks are unstable, and that stability cannot be achieved without frequent synchronizations. We hope that this work dispels that myth and convinces the reader that much perceived clock instability is due to software measurement error. By understanding the sources of clock error, we have built Graham, which can reduce local clock error well below 1ppm using commodity clock sensors. Combined with an accurate synchronization source, Graham can maintain microsecond clock accuracy without additional hardware.

Abstract

Permissioned ledger systems allow a consortium of members that do not trust one another to execute transactions safely on a set of replicas. Such systems typically use Byzantine fault tolerance (BFT) protocols to distribute trust, which only ensures safety when fewer than 1/3 of the replicas misbehave. Providing guarantees beyond this threshold is a challenge: current systems assume that the ledger is corrupt and fail to identify misbehaving replicas or hold the members that operate them accountable—instead all members share the blame.

We describe IA-CCF, a new permissioned ledger system that provides *individual accountability*. It can assign blame to the individual members that operate misbehaving replicas regardless of the number of misbehaving replicas or members. IA-CCF achieves this by signing and logging BFT protocol messages in the ledger, and by using Merkle trees to provide clients with succinct, universally-verifiable *receipts* as evidence of successful transaction execution. Anyone can *audit* the ledger against a set of receipts to discover inconsistencies and identify replicas that signed contradictory statements. IA-CCF also supports *changes* to consortium membership and replicas by tracking signing keys using a sub-ledger of governance transactions. IA-CCF provides strong disincentives to misbehavior with low overhead: it executes 47,000 tx/s while providing clients with receipts in two network round trips.

1 Introduction

Permissioned ledger systems, such as Hyperledger Fabric [4], Quorum [52] and Diem [3], allow a consortium of members that do not trust one another to deploy a trustworthy service on a set of replicas that they operate. These systems typically use protocols for Byzantine fault tolerant (BFT) state machine replication [12, 17, 20, 25, 37, 62] to distribute trust: clients send requests to execute transactions [59, 60] that are executed in a consistent order by the replicas. The results are recorded in a persistent, replicated ledger.

BFT protocols ensure safety (linearizability [29]) and liveness, but they can only do this if fewer than 1/3 of N replicas misbehave. With more misbehaving replicas, current permissioned ledger systems can no longer be trusted. When safety violations are detected, the whole service is deemed to have failed, and all members and replicas share the blame.

Current systems try to avoid this problem by increasing replication [25, 36, 62] or hardening individual replicas [54]. Adding replicas does not help if they are controlled by the same consortium members and thus do not behave independently. Increasing the number of consortium members, however, is challenging or even infeasible in practice. For example, the Diem Association [6] had 26 members, which prevented it from offering a service with more than 26 independent replicas; other consortia are smaller, which results in fewer independent replicas [7, 34, 50]. Even for large consortia with reputable companies, a persistent attacker may slowly compromise $N/3$ replicas over time, e.g., by exploiting lax security practices, bribing members' employees or exploiting software vulnerabilities. Without accountability after a service compromise, there is also no perceived reputational loss that would incentivize members to prevent or disclose these incidents [16, 24, 30].

The Confidential Consortium Framework (CCF) [54] uses trusted hardware [21, 35] to isolate replicas from operators and members, and it provides receipts that commit transaction execution to its ledger. However, CCF does not offer safety or individual accountability if the trusted hardware is compromised.

Prior work explores accountability for various types of distributed systems [1, 26, 27, 38, 64]. PeerReview [27] makes general message passing systems accountable. As we show in §6, applying such a general approach to a permissioned ledger system incurs high overhead: all messages must be signed, and auditing is expensive, because it correlates logs across many replicas. More recent work [14, 19, 53, 56] investigates accountability in BFT protocols and blockchains. These proposals, however, offer no guarantees when 2/3 or more replicas misbehave, because misbehaving replicas may rewrite the ledger history without detection.

We describe *Individual Accountability for CCF* (IA-CCF),

---

a BFT permissioned ledger system that identifies misbehaving replicas and assigns blame to the individual members that operate them, *even if all replicas misbehave*. Individual accountability provides strong disincentives for misbehavior.

IA-CCF is a prototype that extends CCF [54] with support for BFT and individual accountability, while retaining the same user programming model, key-value store, transaction execution engine, and model of governance for changes to the consortium membership and replica set.

IA-CCF supports individual accountability by introducing *Ledger PBFT* (L-PBFT), a new BFT state machine replication protocol that stores ordered transactions in the ledger together with the protocol messages from replicas that justify the execution order. L-PBFT maintains Merkle trees [42] over the ledger, and includes the roots of the trees in protocol messages. Since protocol messages are signed by the replicas, this commits them to the entire contents of the ledger.

IA-CCF then issues *receipts* to clients that provide succinct, universally-verifiable evidence that a transaction executed at a given position in the ledger. Receipts include signed protocol messages from multiple replicas that executed the transaction, thus binding them to a prefix of the ledger.

Given a collection of receipts that violates linearizability, anyone can audit the ledger against the receipts to assign blame to at least $N/3$ replicas. Auditing produces an irrefutable *universal proof-of-misbehavior* (uPoM) in the form of contradictory statements signed by the same replica. The uPoM can be used by an *enforcer*, e.g., a court, to punish the members responsible for the misbehaving replicas. To provide accountability when all replicas misbehave, the enforcer may have to compel members to produce a ledger, imposing sanctions otherwise. While this formally adds a weak synchrony assumption, the enforcer chooses a conservative timeout to make blaming correct members unlikely in practice.

As an example of auditing, a client Alice may have a receipt for a transaction that executed at index i in the ledger and deposited $1 million into client Bob's account. If Bob obtains the receipt from Alice and another receipt for a balance query transaction executed at index j ($j > i$) that does not show the balance, he may conduct an audit: he engages an enforcer to obtain the relevant ledger fragment, and replays the transactions between i and j to check for consistency with his receipts. If Bob is right, auditing produces a uPoM for at least $N/3$ replicas, which Bob sends to the enforcer to punish the consortium members responsible for the replicas.

To support changes to the consortium membership, IA-CCF uses *governance transactions* that alter the set of replicas and consortium members [54]. Governance transactions complicate receipt verification and auditing because they change the signing keys that must be considered. IA-CCF therefore records governance transactions in the ledger, which allows clients, replicas, and auditors to determine the set of valid signing keys. Clients do not need to keep the full ledger, but only receipts of governance transactions. Since

Fig. 1: IA-CCF permissioned ledger system

governance transactions are relatively rare, this *governance sub-ledger* is significantly smaller than the full ledger.

Our IA-CCF prototype provides individual accountability without compromising on throughput or latency: it implements a commitment scheme for transaction batches with only a single signature per replica. This enables clients to receive results with receipts after only two network round-trips. Our evaluation shows that IA-CCF can execute over 47,000 tx/s with low latency.

The contributions of IA-CCF and the paper structure are:

1. L-PBFT, a BFT state machine replication protocol that orders and stores transactions together with the protocol messages justifying the execution order in a ledger (§3.1, §3.2);
2. universally-verifiable client receipts that are generated efficiently with the ledger (§3.3);
3. an efficient auditing approach using the ledger and associated checkpoints, which produces short proofs-of-misbehavior (§4); and
4. a governance mechanism for changing members and replica sets, allowing auditing to assign blame even after members have left (§5).

2 Overview of IA-CCF

Fig. 1 shows IA-CCF's design. An IA-CCF deployment provides a *service*, with a well known name, to *clients*, which are identified by their signing keys. Clients send requests to execute *transactions* by calling stored procedures that define the service logic. Transactions are executed by *replicas* against a strictly-serializable *key-value store* that supports roll-back at transaction granularity. A transaction *request t* reads and/or writes multiple key-value pairs and produces a transaction *result o*.

Consortium *members*, also identified by their signing keys, own the service. They may be added or removed over the service lifetime. For this, members issue *governance transactions*, which change the consortium membership, add or remove replicas, and update stored procedures. The first governance transaction, the *genesis transaction gt*, defines the initial members and replicas. Its hash is the service name.

❶ **Ledger PBFT (L-PBFT)** is a BFT state machine replication protocol used by replicas to order transactions. L-PBFT is based on PBFT [17]. It provides linearizability

and liveness if at most $f = \lceil N/3 \rceil - 1$ out of N replicas fail in a partially-synchronous environment [23].

❷ **Ledger.** L-PBFT maintains an append-only *ledger*, which stores each transaction request t and result o at a ledger index i. Since the consortium membership and the replica set are dynamic, the ledger also records governance transactions. They form a *governance sub-ledger*, which can be used to learn the public signing keys of active replicas and members at any index i.

To assign blame, the ledger also includes *evidence* that a transaction batch was committed by a quorum of replicas. This evidence consists of at least $N-f$ signed L-PBFT protocol messages for a batch. Finally, the ledger stores periodic checkpoints of the key-value store, allowing its state to be reconstructed by replaying the ledger from a checkpoint cp.

All entries in the ledger are bound by Merkle trees. Protocol messages for a transaction batch contain the roots of the Merkle trees. This commits replicas to the whole ledger while allowing succinct existence proofs for entries.

❸ **Receipts** are created by replicas and returned to clients. They bind request execution to members via the replicas' signatures over Merkle tree roots that contains the executed request and the ledger's history. If two or more receipts are inconsistent with any linearizable execution, at least $f+1$ replicas must have signed contradictory statements and can thus be assigned blame.

More precisely, a receipt R for $\langle t, i, o \rangle$ states that request t was executed at index i and produced result o. The receipt consists of $N-f$ protocol messages for t's batch, signed by different replicas, and a path from a Merkle tree root to the leaf that contains an entry for $\langle t, i, o \rangle$.

Clients may obtain receipts from a reply to a request they sent, from replicas, or from other clients. To validate a receipt, clients must check its signatures using the signing keys determined by the governance sub-ledger. A receipt therefore includes the ledger index of the last governance transaction, and clients must obtain the receipt of this governance transaction and all those preceding it. Clients cache governance transaction receipts and fetch missing ones from replicas.

❹ **Auditing** returns a *universal proof-of-misbehavior* (uPoM) if clients obtain receipts that are inconsistent with a linearizable execution. IA-CCF's ledger is universally-verifiable, i.e., anyone can act as an *auditor*: they replay the ledger, check consistency with receipts, and potentially generate a uPoM.

Since all consortium members and replicas may misbehave, an *enforcer*, e.g., a court, must compel members to produce a ledger copy for auditing, sanctioning non-compliance. The enforcer also punishes members based on uPoMs. It is unreasonable to assume that courts could run the service or audit long executions. Therefore, IA-CCF only requires enforcers to re-execute transactions between two consecutive checkpoints to verify a uPoM in the worst case.

After a client passes a sequence of receipts and the governance sub-ledger to the auditor, the auditor confirms the receipts' validity by calculating a Merkle tree root and verifying the replica signatures. It then asks the enforcer to obtain the ledger fragment corresponding to the receipts from the replicas. The auditor checks the validity of the checkpoint cp referenced by the oldest receipt. It then replays the ledger from cp, re-executing transaction requests while checking for consistency with receipts (including governance transaction receipts). If an inconsistency is found at index i, the auditor creates a uPoM $\langle i, \mathcal{F}, cp, R \rangle$ with a ledger fragment $\mathcal{F}$, the checkpoint cp, and the inconsistent receipt R. The uPoM is then forwarded to the enforcer, which imposes penalties on the consortium members blamed.

Threat model, and limitations. We assume a strong attacker that can compromise replicas, clients, auditors, and members to make them behave arbitrarily, but cannot break the cryptographic primitives. We trust the enforcer to assign blame to replicas and the members that operate them only when it verifies a valid uPoM or fails to obtain data for auditing. IA-CCF provides linearizability and liveness if fewer than $1/3$ of the replicas are compromised [17]. With any number of compromised replicas, clients, auditors, and members, IA-CCF never punishes members that operate only correct replicas unless they fail to provide data for auditing. In addition, IA-CCF guarantees that at least $1/3$ of the replicas are blamed, and the members that operate them punished, if clients obtain receipts that are inconsistent with a linearizable execution. The current implementation does not prevent attacks that overwhelm the ledger with transactions to slow down auditing or replaying the governance sub-ledger. It also does not blame replicas for liveness violations, e.g., not returning receipts. Possible defences include: having the enforcer timestamp the genesis transaction and bounding the rate of regular and governance transactions; and forwarding requests to the enforcer and having it monitor protocol execution to assign blame to replicas when receipts are not returned before a deadline. We leave the details of these defences for future work.

3 L-PBFT protocol and receipts

Next, we describe how L-PBFT maintains a ledger with transactions and evidence (§3.1), and how it handles view changes (§3.2). We then explain how evidence is used to create receipts (§3.3) and introduce performance optimizations (§3.4). For ease of presentation, we first assume a fixed replica set; we add dynamic membership in §5.

3.1 Protocol

To support auditing, a BFT state machine replication protocol, such as PBFT [17], must integrate with a ledger: it must ensure that replicas agree on a ledger with both transactions (requests and results) and protocol messages. It must also handle non-determinism to enable replaying the ledger. L-PBFT addresses this issue by agreeing on non-deterministic inputs [18] and using *early execution*: it requires the primary replica to propose a transaction result,

40   Pre: verify (c)
41   M ← M ∪ {c}
```

which the backup replicas must agree on for the batch to commit. L-PBFT then maintains Merkle trees over all ledger entries and puts the trees' roots in protocol message, which ensures that all replicas agree on a serial history of the ledger.

Fig. 2 gives an overview of L-PBFT with early execution: first clients send transaction requests to all replicas. The primary orders the requests, groups them into *batches* and performs early execution. It then sends a pre-prepare message to the backups, which includes the request batch and the execution results. Upon receiving the pre-prepare, the backups execute the requests and confirm that the results match the primary's. If so, they send a prepare message to all other replicas. After a replica receives a pre-prepare and $N-f-1$ matching prepare messages for the same sequence number s and view v, the batch is *prepared* at the replica at v with s if all batches with lower sequence numbers have also prepared. A replica then sends a reply to the clients and commit messages to the other replicas. We say that a batch is *committed* at sequence number s if it has been prepared by $N-f$ replicas in the same view. A client has received a complete response when it has a *receipt* consisting of replies from $N-f$ replicas.
Fig. 2: L-PBFT protocol with early execution and receipts

A naive approach would require each replica to sign two protocol messages, i.e., the pre-prepare/prepare and the commit message, for each committed batch. Instead, L-PBFT uses a novel *nonce commitment* scheme, in which replicas only sign the pre-prepare/prepare messages after including a hashed nonce. Instead of signing the commit, a replica includes the unhashed nonce. This effectively halves the signatures that replicas emit to commit batches successfully.

Alg. 1 presents the pseudocode of L-PBFT. The replica state includes: the current view v and batch sequence number s; a set of transaction requests T waiting to be ordered; a message store M; a nonce store K; a boolean ready indicating if the replica can send/accept pre-prepare messages; a replica identifier r; the key-value store kv; the ledger L; and the Merkle tree M that binds the ledger entries.

In receiveTransactionRequest (line 1), a replica adds a request message to T, where a identifies the invoked stored procedure and its arguments, c is the client identifier, $H(gt)$ is the genesis transaction hash, m_i is the minimum index after which the request can be added to the ledger, and σ_c is the client signature. σ_c and $H(gt)$ ensure that requests cannot be forged or moved to a different ledger, and m_i allows clients to create an ordering dependency between the request and a previously executed transaction.

The function sendPrePrepare (line 4) uses early execution to include the execution result in the batch's Merkle tree root. The primary $p = v \bmod N$ collects a batch of transaction requests, executes them, and appends them to a new Merkle tree G. Then, the primary retrieves the commitment evidence P_{s-P} and K_{s-P} for the batch at $s-P$ from the message store M and appends it to the ledger. E_{s-P} is a bitmap that records the replicas that supplied commitment evidence.

Next, the primary creates the pre-prepare message with the hash of a fresh nonce $K[v,s]$, the root of the Merkle trees, $\bar{M}$ and $\bar{G}$, and signs it. G is a Merkle tree that contains all $\langle t,i,o \rangle$ entries in a batch. The complete pre-prepare message has two extra fields: i_g, the index of the last governance transaction, which allows clients to verify receipts with a changing set of replicas (see §5.2); and d_C, a digest of the key-value store state at the last checkpoint, which enables auditing from a checkpoint without replaying the ledger from the start (see §4).

By signing $\bar{M}$, the primary commits to the contents of the ledger, including the commitment evidence for $s-P$ that it retrieved and added to the ledger. It is important for the primary to order the evidence to ensure that replicas agree on the
Fig. 3: Ledger with evidence and Merkle trees

ledger: if replicas added their own evidence to the ledger when they received prepare and commit messages, their ledgers could diverge. The commitment evidence $\mathcal{P}_{s-P}$ contains $N-f-1$ prepare messages for sequence number $s-P$ and view v that match the pre-prepare at sequence number $s-P$ in the ledger. $\mathcal{K}_{s-P}$ are the $N-f$ nonces with hashes in the pre-prepare/prepare messages in $\mathcal{P}_{s-P}$. This evidence is sufficient to prove to a third party that the batch at $s-P$ prepared at $N-f$ replicas and therefore committed with s. The pre-prepare message along with the leaves of G are then added to the ledger.

The primary communicates its ordering decision by sending the pre-prepare message to all replicas, together with a list $\mathcal{B}$ of the hashes of transaction requests in execution order. The requests are sent separately by the clients, and the commitment evidence for $s-P$ is not included in the message. The pre-prepare messages are $O(N)$ in size but the constant is small. Our implementation uses 8 bytes in the E_{s-P} bitmap to support up to 64 replicas, making the pre-prepare messages effectively $O(1)$.

Fig. 3 gives an example of the ledger state after this step. For each transaction in the batch, the primary adds a ledger entry in the order executed. The entry for T_i has the form $\langle t,i,o\rangle$ where o includes the reply sent to the client and the hash of the transaction's write-set; pp_s is the pre-prepare for s, and $\mathcal{P}_{s-P}$ and $\mathcal{K}_{s-P}$ are evidence that the batch at sequence number $s-P$ committed. L-PBFT pipelines the ordering of up to $P \geq 1$ concurrent batches to improve performance. Therefore, the commitment evidence lags P behind s, because it is unavailable when the primary sends the pre-prepare for s. Appx. A, Lemma 2 shows that *early execution* maintains linearizability.

When a backup replica receives the pre-prepare (line 15), it rejects the message if it already sent a prepare for the same view and sequence number ($\mathcal{K}[v,s] \neq$ nil). Otherwise, it checks if it already has the requests and commitment evidence referenced by the pre-prepare. Replicas store received requests, prepare, and commit messages in non-volatile storage ($\mathcal{M}$) until they receive (or send) a corresponding pre-prepare. To reduce network load, the primary does not resend requests or messages used as commitment evidence. If the backup is missing messages, it requests that the primary retransmit them, because a correct primary is guaranteed to have them.

The backup then executes the requests in the order prescribed by the primary, and adds the resulting transaction entries to a new Merkle tree G (line 19). Then, it adds the same $\mathcal{P}_{s-P}$ and $\mathcal{K}_{s-P}$ as the primary to the ledger. At this point, the ledger at the backup should be identical to the one at the primary just before the pre-prepare message is added. The backup checks that the roots of its Merkle trees match $\bar{M}$ and

$\bar{G}$ in the pre-prepare, respectively. If not, the message is rejected, the entries for batch s are removed from the ledger, and the transactions are rolled back. Otherwise, the backup adds the pre-prepare to the ledger, followed by the leaves of the Merkle tree G, and sends a matching prepare message with the format $\langle\text{prepare},r,H(\mathcal{K}[v,s]),H(pp)\rangle_{\sigma_r}$, where $H(\mathcal{K}[v,s])$ commits a fresh nonce, and $H(pp)$ is the pre-prepare's hash.

L-PBFT ensures deterministic transaction execution by agreeing on non-deterministic inputs [18]. Line 22 ensures that a backup's execution of batch $\mathcal{B}$ and its ledger are identical to those of the primary by comparing the Merkle roots $\bar{G}$ and $\bar{M}$. If this check fails, the backup rolls back execution and attempts to view change (§3.2). This way divergent execution due to bugs, i.e., failing to identify non-deterministic inputs, can affect liveness but not diverge the ledger.

In batchPrepared (line 30), the nonce commitment and early execution allow replicas to return replies to clients in two message round trips without signing reply or commit messages. When the batch prepares at replica r, it sends a commit message with the format $\langle\text{commit},v,s',r,\mathcal{K}[v,s']\rangle$ where $\mathcal{K}[v,s']$ is the nonce the replica committed to in the pre-prepare/prepare messages that it sent for v and s'. Since the nonce $\mathcal{K}[v,s']$ is revealed to clients and replicas only when a replica prepares the batch having a pre-prepare/prepare message and the corresponding nonce can prove to a third party that the replica prepared the batch at v and s' (see Appx. A, Lemma 3).

Finally, a replica r commits a prepared batch v,s' after it receives $N-f$ commit messages, including its own. The nonce hashes in the commit messages must match the ones in the pre-prepare/prepare messages.

We prove that L-PBFT produces a linearizable execution order in Appx. A, Thm. 1.

3.2 View changes

During the L-PBFT protocol execution, the primary may misbehave or be slow, which requires a *view change*. The change of the primary must be done in a manner that does not preclude auditing, which is a new requirement that goes beyond PBFT's view change protocol. L-PBFT view changes are auditable and must provide proof that a batch's re-execution produces the same result as the original execution.

L-PBFT addresses this as follows: it sends the evidence that batches prepared during view changes and includes the Merkle tree root $\bar{G}$ of a batch and its execution in the *pre-prepare* message, which ensures that batches are re-executed consistently. During a view change, each replica sends a view-change message with information about prepared requests. The primary for a new view v' sends a new-view message backed by $N-f$ view-change messages for v'. For each sequence number with a prepared batch in the view-change messages, the primary picks the batch that prepared with the largest view and proposes it in v'. Since all committed requests have also prepared, this ensures linearizability with batch execution ordered by the sequence

19    Pre: isPrimary (r',v)
             ∧ hasRequests (T,PP_mv) ∧ hasEvidence (M,PP_mv)
             ∧ r' ≠ r ∧ ¬ready ∧ |getViewChanges(M,E_vc,h_vc)| > N−f
20    ⟨M̄',PP'_ov⟩ = processViewChanges(getViewChanges(M,E_vc,h_vc))
21    if M̄' = M̄ then
22       │  L ← L || nv; M ← M || nv
23       │  if ready ← processPreparesInNewView(PP_mv,PP'_ov) then return
24    undo(nv,s,M,L)
```

Alg. 3: Verifying Receipts

```
1  on verifyReceipt (⟨t,i,o⟩,⟨v,s,M̄,H(k_p),E_{s−P},i_g,d_C⟩,σ_p,E_s,Σ_s,K,S⟩)
2     Ḡ' ← pathHash (⟨t,i,o⟩)
3     foreach G_i ∈ S do
4       │  Ḡ' ← pathHash (Ḡ', G_i)
5     pp = ⟨pre-prepare,v,s,M̄,Ḡ',H(k_p),E_{s−P},i_g,d_C⟩
6     if not checkSignature (σ_p, pp) then   return false
7     foreach r ∈ E_s do
8       │  if r = p ∧ H(K[p]) ≠ H(k_p) then   return false
9       │  if r ≠ p ∧ not checkSignature
             (Σ_s[r], ⟨prepare,r,H(K[r]),H(pp_{σ_p})⟩) then   return false
10    return true
```

by adding an entry with the $N-f$ view-change messages that it accepted to the ledger in order of increasing replica identifier; h_{vc} is the hash of that entry and E_{vc} is a bitmap with the replicas that sent the messages. It returns the root of the Merkle tree $\bar{M}$, E_{vc}, h_{vc}, and PP_{ov} (line 14). The primary appends the new-view to the ledger, sends it to all replicas, resends the prepared batches in pre-prepare messages in the new view, and adds them to the ledger.

When backups receive the new-view (line 18), they obtain missing view-change messages, requests and evidence that it references, and call processViewChanges. If it returns a Merkle tree root equal to the one in new-view, they accept the message, add it to the ledger, and process the pre-prepare messages PP_{nv}. If these match the batches and evidence in PP'_{ov} for the same sequence numbers, they are added to the ledger; otherwise, all changes are undone.

3.3 Receipts

To allow third parties to audit the ledger against the transaction results returned to clients, L-PBFT returns *receipts*, which are statements signed by $N-f$ replicas that a transaction request t executed at index i and produced a result o. L-PBFT exploits the per batch Merkle tree G together with the nonce commitment scheme (§3.1) to avoid having replicas sign the reply for each request.

Creating receipts. When a transaction batch described by pre-prepare pp prepares at replica r, view v and sequence number s' (Alg. 1, line 30), it sends $\langle \text{reply},v,s',r,\sigma_r,K[v,s']\rangle$ to every client with a transaction in the batch. (If the client has multiple transactions in the batch, only one reply is sent.) By revealing the nonces, the replicas provide the client with proof that they claimed to have prepared the batch without a signed reply.

Only a designated replica, chosen based on t, sends the result and the rest of the receipt to the client (line 36). The replica computes a list of sibling hashes S along the path from the leaf to the root of the per-batch Merkle tree G. For the example of T_i in Fig. 3, S consists of the digest of T_{i-1} and G_1, which is sufficient to recompute $\bar{G}$ given T_i. It then sends the client $\langle \text{replyx},v,s',\bar{M},H(k_p),E_{s'-P},i_g,d_C,H(t),i,o,S\rangle$, where i_g and d_C are used for auditing.

Verifying receipts. The client waits for $N-f$ replicas to send reply messages with the same v and s, and for a replyx message with the same v and s. It then recreates the pre-prepare

numbers at which batches committed.

Alg. 2 formalizes the pseudocode for view changes. If the primary for view v appears faulty or slow, a replica sends a view-change message, $\langle \text{view-change},v+1,r,PP\rangle_{\sigma_r}$, to all other replicas (line 1), where PP contains the last P pre-prepare messages that prepared locally (line 3). Only the last message in PP is required to provide linearizability, because it includes the Merkle tree roots $\bar{M}$ and $\bar{G}$ that determine the ledger contents up to that point. The other pre-prepare messages are used during auditing to verify that replicas reported the batches they prepared in view-change (§4).

When replicas receive a view-change message (line 6), before processing it, they fetch missing prepare messages from the sender to prove that the last pre-prepare in PP has prepared. When replicas increment v, they set ready to false (lines 4, 11), which ensures that they do not send or accept pre-prepare messages until they have completed the new-view.

After accepting $N-f$ view-change messages for the new view (line 12), the new primary calls processViewChanges, which picks the view-change message vc_{lp} with the last prepared pre-prepare message pp_{lp} from those with the largest view number. It then updates the ledger to match the Merkle roots in pp_{lp} by fetching missing ledger entries from replicas that sent matching prepare messages. Since at least $f+1$ of those are correct, this is always possible. The primary checks that all messages in PP of vc_{lp} appear at the right ledger positions; if not, it discards vc_{lp} and re-tries (omitted from Alg. 2).

Next the primary resets the ledger to $s_{lp}-P$, because the batches up to this point are guaranteed to have committed. It saves all the request batches and commitment evidence for sequence numbers between $s_{lp}-P$ and s_{lp} and returns it in PP_{ov}. This is needed to resend pre-prepare messages for the prepared batches in the new view. The function ends

and prepare messages (Alg. 3, line 6), with the information in replyx and the hashes of the nonces, and verifies the signatures. (We describe how to determine N and verify signatures under dynamic membership in §5.2.) This step is shared across all transaction requests that the client may have sent in the batch.

IA-CCF uses the Merkle tree G to bind signatures in pre-prepare and prepare messages to transactions in the batch, enabling replicas to produce a single signature per batch. In the example in Fig. 3, the client checks if $\bar{G} = H(H(H(T_{i-1})\|H(\langle t, i, o\rangle))\|G_1))$ (lines 2–4). If the hashes match, the client has a valid receipt, i.e., a statement signed by $N-f$ replicas that a request t executed at index i and produced a result o; otherwise (or if the client does not receive replies before a timeout), it retransmits the request and selects a different replica to send back replyx. (The application is responsible for ensuring exactly-once semantics if needed.)

Clients store the receipt for $\langle t, i, o \rangle$ as $\langle v, s, \bar{M}, H(k_p), E_{s-P},$ $i_g, d_C, \sigma_p, E_s, \Sigma_s, \mathcal{K}_s, \mathcal{S} \rangle$ where Σ_s is a list of the signatures in prepare messages, $\mathcal{K}_s$ is a list of nonces, and E_s is a bitmap indicating the replicas with entries in Σ_s, and $\mathcal{K}_s$, sorted in increasing order of replica identifier. All receipt components, including common hashes in $\mathcal{S}$, are shared across requests in the same batch.

Clients must store the receipts together with the transaction request and the corresponding result to resolve future disputes. This is not a burden because receipts are concise: all components have constant size, except $|\mathcal{S}|$, whose number of entries is logarithmic in the number of requests in a batch; Σ_s and $\mathcal{K}_s$ have up to $N-f$ entries. In addition, most intermediate hashes in $\mathcal{S}$ can be shared across collections of receipts. We explored using signature aggregation [13] to reduce the size of Σ_s, but, for realistic consortia sizes, verifying the signatures becomes more expensive than our current implementation.

3.4 Performance optimizations

L-PBFT includes several optimizations to improve transaction and auditing throughput.

Checkpoints in L-PBFT allow new replicas to start processing requests without having to replay the ledger from the start (§5.1); slow replicas to be brought up-to-date using a recent checkpoint; and auditing to start from a checkpoint instead of the beginning of the ledger(§4.1).

Checkpoints include the key-value store and the Merkle tree M's newest leaf, root, and the connecting branches. Replicas create a checkpoint cp_s when they execute a batch with sequence number s such that $s \bmod C = 0$. The primary adds a batch to the ledger at sequence number $s+C$ with a special *checkpoint transaction*, which records the checkpoint digest. C is chosen to give replicas enough time to complete a checkpoint without delaying L-PBFT execution. Backups only accept the pre-prepare for $s+C$ if they compute the same checkpoint digest for sequence number s.

When a replica fetches checkpoint cp_s, it also retrieves the ledger up to s. It does not need to replay the ledger or check all signatures (with the exception of governance transactions; §5.2). Instead, it checks the signatures in checkpoint receipts and that the ledger contents between consecutive checkpoints are consistent with the Merkle tree roots in the corresponding receipts. This is done from the start of the ledger until $s+C$.

Cryptography. L-PBFT reduces the impact of cryptographic operations. Signature verification is parallelized for messages received from replicas and clients [12, 20] to improve throughput and scalability. All messages are sent over encrypted and authenticated connections, even signed messages. This mitigates denial-of-service attacks that consume replica resources verifying signatures [20].

To further improve performance, backups overlap the execution of request batches with the validation of pre-prepare signatures. They only send the prepare after both completed. Since pre-prepare messages are received over authenticated connections, this always succeeds for correct primaries.

4 Auditing and enforcement

In this section, we describe how auditing produces *universal proofs-of-misbehavior* (uPoMs) when linearizability is violated (§4.1), and the role of the enforcer in obtaining ledgers for auditing and punishing the members responsible for misbehaving replicas (§4.2). We first focus on the simpler case of auditing without governance transactions; §5 describes governance transactions and their impact on auditing.

4.1 Auditing

An audit is triggered when someone, usually a client, obtains a sequence of transaction receipts that violate linearizability, i.e., when no linearizable execution of the stored procedures that define the transactions can produce the sequence of receipts. The mechanism to detect linearizability violations is application dependent. It involves clients, which interact through a sequence of transactions, exchanging receipts and using the application semantics to reason about the correctness of the receipt sequence. We describe a banking-inspired example in the introduction.

The goal of auditing is to detect dishonest behavior regardless of the number of misbehaving replicas, i.e., it must find proof of misbehavior even if all replicas collude and rewrite the ledger. IA-CCF therefore tightly integrates the ledger with receipts—even if the ledger is rewritten, the misbehaving replicas are unable to alter the receipts.

An audit can be performed by anyone, and begins when an *auditor* receives a collection of receipts. Next, the auditor requests a *checkpoint* and a *ledger fragment* that contains the section of the ledger spanning the receipts. Any honest replica that signed the receipts is guaranteed to have the checkpoint and ledger fragment. When the auditor receives the requested data, it verifies the ledger structure by checking the protocol messages and their order, and validating any signatures in the ledger—but it does not re-execute transactions. Then, the auditor checks that the transactions referenced by the receipts

are present at the right positions in the ledger.

If the above steps have not discovered misbehavior, there remains the possibility that at least $N-f$ of the replicas colluded and agreed on an incorrect execution result. Therefore, the auditor loads the checkpoint and replays the transactions from the ledger fragment to check if execution results are correct. Throughout this process, if dishonest behavior is uncovered, the auditor can produce a universally-verifiable proof that at least $f+1$ replicas misbehaved.

More formally, Alg. 4 presents the pseudocode for the auditing process. First, the auditor receives an ordered set of receipts $\mathcal{R} = \{\langle\langle t_0, i_0, o_0\rangle, x_0\rangle, ..., \langle\langle t_k, i_k, o_k\rangle, x_k\rangle\}$ where $k \geq 1$ and $\forall l \in [0,k): s_l \leq s_{l+1}$. Here, s_i is the sequence number that is specified in x_i. The auditor invokes auditReceipts (line 2) to check if the receipts are valid and the minimum index requirements have been satisfied. If there is a receipt that violates the requirement in the request, all replicas that have signed the receipt can be blamed.

After that, the auditor must obtain a ledger fragment and checkpoint that are *complete* in relation to $\mathcal{R}$ (line 3). We formally define completeness in Appx. B, but intuitively the ledger fragment must be (i) *well-formed*; (ii) include all batches and evidence between sequence numbers s_{C_0} and s_k where s_{C_0} is the sequence number of the checkpoint transaction that is linked in the first receipt; and (iii) include view-change messages for all views in $\mathcal{R}$. The transaction and checkpoint at s_{C_0} must match the checkpoint linked in the first receipt. A ledger fragment is *valid* if it can be produced by a sequence of correct primaries in a sequence of views where there are at most f Byzantine failures. It is well-formed if it is valid, or if it would be valid if not for the incorrect execution of some transactions and/or checkpoints. A correct replica always maintains a well-formed ledger.

In getCheckpointAndLedger (line 3), the auditor, with the help of an *enforcer*, obtains ledger fragments and checkpoints from replicas that signed the latest receipt with the highest view number in $\mathcal{R}$ (line 10). The auditor checks if responses are complete in relation to the receipts. If a ledger fragment is not well-formed or misses the required view-change messages, the auditor can blame the responding replica. Below, we assume that the responses contain no invalid signatures, we show in Appx. B how the auditor handles that case.

If the batch at s_{C_0} is not a checkpoint or the checkpoint digest does not match the first receipt, the auditor can assign blame to the intersection of replicas that have signed the batch at $s_{C_0} + C$ and the first receipt, as the checkpoint reference in a receipt must always link to the last committed checkpoint. If the fragment is not long enough to include the sequence number in one of the receipts, there must be misbehavior during a view change. The auditor can then blame at least $f+1$ misbehaving replicas: the intersection of the replicas that participated in a view change and that also signed the receipt. A correctness proof and the details of obtaining a complete ledger fragment and checkpoint are

---

29             uPoM←⟨iᵢ,F,cp⟩; send(uPoM); return
30       if s mod C=0 then
31          s_cp←s; cp←createCheckpoint(kv)
```

described in Appx. B, Lemmas 4 and 6.

After obtaining a well-formed ledger, in verifyReceiptsInLedger (line 4), the auditor compares the receipts with the ledger. If a receipt $\langle\langle t_k, i_k, o_k\rangle, x_k\rangle$ does not match the batch at s_k in the ledger fragment, we show in Lemma 5 that the auditor can assign blame to $f+1$ misbehaving replicas. In summary, there are three cases: (i) the pre-prepare with sequence number s_k in L has a view number $v_l = v_k$; (ii) $v_l > v_k$; or (iii) $v_l < v_k$. In case (i), the ledger fragment contains evidence that the batch with sequence number s_k has prepared at $N-f$ replicas. Since at least $f+1$ of the replicas that have prepared the batch also signed the receipt, they can be blamed. In case (ii), since $v_l > v_k$, there must be at least $N-f$ view-change messages from different replicas that transition to a view greater than v_k in the ledger fragment but claim not to have prepared the batch in the receipt in view v_k. Since there are at least $f+1$ of those replicas that also signed the receipt, they can be blamed. In case (iii), since $v_k > v_l$ and the ledger fragment is complete in relation to the receipt, there must be at least $N-f$ view-change messages from different replicas that transition to a view greater than v_l in the ledger fragment. Similarly, the intersection of those replicas and the ones that signed the receipt can be blamed.

Since $N-f$ or more replicas may have misbehaved, it is necessary to replay transaction execution to check if the results are correct. The auditor does not need to understand the semantics of the service; it can retrieve the code of the stored procedures from C_0. The auditor sets the service state to the checkpoint value and replays transactions. If replaying a transaction fails to match the result in the ledger, the auditor can

assign blame to any replica that signed the batch that contains the transaction. This is shown in replayLedger (line 5).

4.2 Enforcement

Since IA-CCF provides individual accountability even if all replicas and members misbehave, there must be an *enforcer* outside of the system to obtain checkpoints and ledger fragments for auditing, and to punish members responsible for misbehaving replicas. For example, consortium members may sign a binding contract to establish penalties if a uPoM proves that one of their replicas misbehaved, or if they fail to produce checkpoints and ledgers for auditing by an agreed deadline. These penalties may be imposed by the enforcer via arbitration [8] or a court of law [9].

The enforcer receives a set of receipts $\mathcal{R}$ from the auditor (Alg. 4, line 10). It then verifies that the receipts are valid, and requests all of the replicas that signed the latest receipt with the highest view for a ledger fragment that is complete in relation to $\mathcal{R}$.

Correct replicas will respond to the enforcer quickly. If the enforcer does not receive a response from a replica within a reasonable duration, e.g., within minutes, it contacts the controlling consortium member to obtain the checkpoint and ledger. If the member fails to provide this information by an agreed deadline, e.g., within days, it is punished according to the contract. This is important to ensure that misbehaving members cannot escape punishment by failing to produce information for auditing. However, it introduces a weak synchrony assumption that may lead to the punishment of honest but slow members. We expect that the deadline will be chosen conservatively to make this unlikely in practice. After the deadline elapses, the enforcer either returns to the auditor $f+1$ responses, or it penalizes $f+1$ unresponsive replicas.

The enforcer also punishes members if a uPoM proves that one of their replicas misbehaved. When it receives a uPoM, it checks its validity by carrying out an audit, as described in §4.1, but the ledger fragment size and the number of transactions to replay is bounded by the transactions between two consecutive checkpoints. Furthermore, if there are fewer than $N-f$ misbehaving replicas, the uPoM does not require the enforcer to replay transactions. If the uPoM is incorrect, the enforcer punishes the auditor; otherwise, it punishes the members responsible for at least $f+1$ misbehaving replicas.

In practice, we expect the load placed on the enforcer to be small, because auditing is rare—IA-CCF provides linearizability with up to f misbehaving replicas and the enforcer penalizes entities that request information for auditing and fail to produce a valid, minimal uPoM.

5 Reconfiguration and auditing

In this section, we describe how IA-CCF can change the consortium membership and the active replica set (§5.1). We explain how this impacts receipt validation (§5.2) and auditing (§5.3).

5.1 Reconfiguration

An IA-CCF deployment must handle changes to the active member and replica set while supporting auditing, regardless of how many replicas misbehave. For this, IA-CCF maintains governance data in the form of a *configuration*, which includes the public signing keys for members and replicas and an endorsement of each replica's signing key signed by the member responsible.

Changing the configuration enables members to change the active replica set. This is initiated by a *referendum*: members propose an updated configuration followed by the other members voting on the proposal. The number of votes required to pass the proposal is part of the service's state.

When voting on proposals, members must ensure the integrity of the service, e.g., disallowing an individual member from controlling too many replicas. Members are also limited to adding or removing at most f replicas, which ensures that the configuration change does not effect the service's liveness.

A referendum is carried out through governance transactions: a member proposes a new configuration by sending a *propose* transaction request. This is followed by members sending *vote* requests. Upon executing the final *vote* transaction required for a referendum to pass at sequence number s, the primary ends the current batch, and initiates the reconfiguration process.

A *reconfiguration* first adds evidence for the referendum to the ledger. This is done as part of the old configuration by the primary sending P pre-prepare messages without batched requests, called the *end-of-configuration* batches. The pre-prepare message for the end-of-configuration batch at sequence number $s+P$ contains evidence that the batch at s committed (§3). In addition, these pre-prepare messages include an extra field: the *committed* Merkle root, which is the root of the Merkle tree at s. This evidence is required for auditing: it commits the replicas that signed the P^{th} end-of-configuration batch to triggering the reconfiguration. Similarly, the signatures of the replicas that prepared the P^{th} end-of-configuration batch must be included in the ledger in the same configuration. Following the first P end-of-configuration batches, the primary pre-prepares another set of P end-of-configuration batches. The configuration change takes effect at $s+2P$.

The replicas in the new configuration create a checkpoint of the key-value store at sequence number $s+2P$. The primary creates a pre-prepare for the checkpoint at $s+2P+1$, followed by P *start-of-configuration* pre-prepare messages with empty request batches. This ensures that a correct replica commits the checkpoint transaction before other transactions are executed in the new configuration. If any of the end/start-of-configuration batches correspond to a checkpoint sequence number, the checkpoint is skipped. Therefore, the checkpoint digests d_c in the pre-prepare messages always refer to checkpoints in the same configuration.

A newly added replica first obtains the ledger and a recent

checkpoint, and replays the ledger from that checkpoint (§3.4). Replicas that are no longer part of the new configuration retire after sending the pre-prepare for $s+2P$. Removed members and replicas should delete their private signing keys to provide forward security. This prevents them from being blamed for future compromises, while still allowing authentication of transactions in the ledger using their public keys.

5.2 Governance sub-ledger and receipts

When a client verifies a receipt, it must know which replicas were active when the receipt was created. IA-CCF addresses this with the help of the governance sub-ledger.

Governance transactions are recorded in the ledger and used by auditors to determine the active configuration. Clients, however, do not have a copy of the ledger, but need to verify receipt signatures. To do this, they store receipts for all governance transactions and, for each reconfiguration, they also store the receipts for the P^{th} end-of-configuration batch. We refer to this as the receipts of the *governance sub-ledger*. A client checks that a transaction receipt for index i is valid by considering the governance sub-ledger from the genesis transaction gt up to i. The client verifies the governance receipts, and if successful, the replica signing keys at index i are used to validate the receipt (§3).

This raises the challenge of how a client determines that it has *all* required governance receipts. IA-CCF includes the ledger index of the last governance transaction in each pre-prepare message and receipt (i_g). A client can request missing receipts from replicas by traversing the sequence of governance receipts. It verifies received receipts incrementally and caches them locally.

With reconfiguration, the definition of a valid receipt is extended: a valid receipt R must include valid governance receipts from gt up to the configuration that produced R.

5.3 Auditing

Reconfiguration introduces several new tasks for the auditor: it must consider the governance sub-ledger with receipts; validate that reconfigurations were executed correctly; and ensure that that only one configuration was active for any given index or sequence number. Next, we provide a summary of the required changes to the auditing process; a detailed correctness proof is included in Appx. B.2.

A client initiates an audit by sending inconsistent receipts and the supporting governance receipts to an auditor. The auditor replays these governance transactions to determine the signing keys required to verify each client receipt. After verifying the receipts, the auditor requests a ledger fragment and checkpoint from the enforcer.

The auditor may uncover that multiple configurations were active for a given index or sequence number, this can happen when misbehaving replicas fork or rewrite the ledger. We call this a *fork in governance*. If the auditor finds a fork, there are two P^{th} end-of-configuration batch receipts with the same preceding configuration that are not *equivalent*: they are at different indices or sequence numbers, or their pre-prepare messages do not contain the same committed Merkle root, i.e., they are not preceded by the same governance transactions. In this case, the auditor assigns blame to the replicas that signed both receipts, as a correct replica that prepares a P^{th} end-of-configuration batch commits the final *vote* transaction that triggers reconfiguration.

If the enforcer cannot obtain the required information for a valid receipt R from the sequence of provided receipts, there must be misbehaving replicas. In addition to the misbehavior described in §4.1, the misbehaving replicas may have created a fork in governance or incorrectly prepared the P^{th} end-of-configuration batch that succeeds the configuration that produced the receipt R (see Lemmas 8 and 11).

Another possibility is that the configuration that produced a receipt R for a sequence number s may not match the configuration that prepared the batch at s in a well-formed ledger fragment. In this case, blame is again assigned to the replicas that signed R and prepared the P^{th} end-of-configuration batch that succeeds the configuration that produced R (see Lemma 9).

After assigning blame, the auditor sends a uPoM to the enforcer with the supporting governance receipts.

6 Evaluation

We evaluate IA-CCF to understand the cost of providing receipts (§6.1), its scalability (§6.2), the overheads of receipt validation (§6.3), and auditing (§6.5). We finish with a performance breakdown of IA-CCF's design features (§6.8).

Testbeds. Our experimental setup consists of three environments: (a) a dedicated cluster with 16 machines, each with an 8-core 3.7-Ghz Intel E-2288G CPU with 16 GB of RAM and a 40 Gbps network with full bi-section bandwidth; (b) a LAN environment in the Azure cloud, with Fsv2-series VMs with 16-core 2.7-GHz Intel Xeon 8168 CPUs and 7 Gbps network links; and (c) a WAN environment with the same VMs across 3 Azure regions (US East, US West 2, US South Central). All machines run Ubuntu Linux 18.04.4 LTS.

Implementation. Our IA-CCF prototype is based on CCF v0.13.2 [45] and has approx. 40,000 lines of C++ code. It uses the formally-verified Merkle trees and SHA functions of EverCrypt [51], the MbedTLS library [41] for client connections, and secp256k1 [61] for all secure signatures. Replicas create secure communication channels using a Diffie–Hellman key exchange.

Pipelining batch execution (P in Alg. 1) improves IA-CCF's throughput. We use $P=2$ for the LAN and $P=6$ for the WAN, with maximum batch sizes of 300 and 800 requests, respectively. Checkpoints are created every 10K or 4K sequence numbers in the LAN and WAN environments, respectively.

Benchmarks. We use the *SmallBank* benchmark [2], which models a bank with 500K customer accounts. Clients randomly execute 5 transaction types: deposit, transfer, and withdraw funds; check account balances; and amalgamate ac-

Tab. 1: Size of ledger entries (SmallBank)

Ledger entry type	Size (bytes)	
	f = 1	f = 3

	average latency	99th percentile latency	network round trips
IA-CCF	183 ms	194 ms	2
HotStuff	340 ms	393 ms	4.5

Fig. 5: Transaction throughput vs. replica count (WAN)

counts. The size of the ledger entries is shown in Tab. 1 where only the Prepare Evidence and Nonces entries depend on f.

Since IA-CCF's design targets accountability with more than f failures, we omit results from experiments with fewer failures. In such cases, IA-CCF's performance matches that of prior work, because it uses well-established BFT techniques, such as view changes, sending messages via authenticated channels and client-signed requests [12, 20]. Instead, we consider the performance of receipt validation (§6.3) and auditing (§6.5), which are new contributions of IA-CCF.

Transaction throughput is measured at the primary replica and latency at the clients. All experiments are compute-bound. Results are averaged over 5 runs, with min/max error bars.

Baselines. We compare against four baselines: IA-CCF-PeerReview, which uses PeerReview for accountability [27], i.e., replicas sign all messages and send signed acknowledgements for all messages; IA-CCF-NoReceipt, an IA-CCF variant that produces a ledger but no receipts; HotStuff [62], a state-of-the-art BFT protocol, which is at the core of the Diem permissioned ledger system [3]; and Hyperledger Fabric (v. 2.2) [4], a popular open-source permissioned ledger system. We compare against Fabric's latest major release that does not include a BFT consensus protocol [33] and only tolerates crash failures using Raft [49].

6.1 Transaction throughput and latency

We explore the throughput and latency of transaction execution with 4 replicas ($f=1$) in the dedicated cluster, comparing IA-CCF, IA-CCF-NoReceipt, IA-CCF-PeerReview, and Fabric.

Fig. 4 shows a throughput/latency plot as transaction load increases. IA-CCF achieves 47,841 tx/s while maintaining latencies below 70 ms. As the load increases, queueing delays increase latency. IA-CCF-NoReceipt's throughput is 51,209 tx/s, which is only 3% higher than IA-CCF, demonstrating the low cost of receipts.

IA-CCF-PeerReview exhibits an order of magnitude lower
throughput because all messages must be signed, e.g., a replica must sign a reply message for each transaction in a batch. This causes IA-CCF-PeerReview to perform two orders of magnitude more asymmetric cryptographic operations than IA-CCF.

Fabric's throughput is only 1,222 tx/s, with a latency of 1.9 s. This is substantially worse than IA-CCF, despite not using a BFT protocol. Our analysis reveals two reasons: Fabric's *execute-order-validate* model requires that replicas issue a signature for each executed transaction, while IA-CCF replicas only require one signature per batch; and Fabric suffers from documented inefficiencies related to its key-value store implementation [48].

6.2 Scalability

Next we consider the effect on transaction throughput when increasing the number of IA-CCF replicas in the Azure WAN environment, spanning multiple regions to reduce correlated failures [10]. We compare against IA-CCF deployed in the Azure LAN environment, IA-CCF-PeerReview, and HotStuff, a BFT consensus protocol without a ledger or key-value store.

Fig. 5 shows that, as expected, IA-CCF's throughput decreases with more replicas because more signatures are verified by each replica. Since each replica has a fixed number of threads for checking signed pre-prepare/prepare messages in parallel, throughput decreases when the replica count exceeds the number of hardware threads, which is only 16 in this deployment. IA-CCF is only marginally affected by the higher WAN latencies due to its use of pipelining, as shown by the comparison to the LAN deployment.

HotStuff [63] achieves a throughput of 5,862 tx/s in the WAN environment, which is worse than its reported LAN throughput [66]. While it degrades slowly with more replicas, even with 64 replicas its throughput remains 71% lower than that of IA-CCF. The throughput of IA-CCF-PeerReview is even lower since it performs more cryptographic operations.

We also measure the request latency of HotStuff and IA-CCF under low load. As reported in Tab. 2, HotStuff's request latency is approximately twice that of IA-CCF's. For

(a) 100,000 accounts **(b) 500,000 accounts** **(c) 1,000,000 accounts**
Fig. 6: Transaction throughput/latency when varying the number of accounts and checkpoint interval (f=1, dedicated cluster)

both systems, request latency is dominated by the number of network round trips and clients receive transaction results with receipts in only 2 round trips in IA-CCF.

6.3 Receipt validation

We measure the time required to verify receipts, which depends on (i) the length of the path in the Merkle tree G and (ii) the number of signatures to be checked. Since the number of leaves in G is bounded by the batch size, the path length remains small: verification takes 2.1 µs and 2.3 µs for batches of 300 and 800 requests, respectively. The overall cost is dominated by the signature verification, which takes 18 ms and 52 ms for f=1 and f=3, respectively.

6.4 Governance sub-ledger

Next, we consider the size of the governance sub-ledger, which is stored by clients. The sub-ledger is a collection of receipts for every transaction that has updated the governance of an IA-CCF deployment. A receipt's size is 623 bytes or 1,565 bytes for f=1 or f=3, respectively. In addition, the client must store the governance request and the corresponding response, which have variable size. We expect governance operations to be rare. Therefore, storing and verifying governance sub-ledger receipts has low overhead.

6.5 Ledger auditing

Next, we want to understand auditing performance. For the SmallBank workload, we compare execution time to auditing time. When measuring throughput at f=1, auditing is 23% faster than execution, because there is no network overhead, message signing, or ledger writes. In each batch, IA-CCF only verifies $2f$+1 rather than up to $3f$+1 signatures. For f=4, the performance gap increases to 67%, as more replicas add communication and cryptographic load during execution. We observe that the bottleneck for auditing is verification of client request signatures, which can be trivially parallelized.

6.6 Key-value store

We explore the performance impact of varying the number of entries in the key-value store by varying the number of Small-Bank accounts. Fig. 7 shows a throughput vs. latency plot. As expected, throughput decreases when the number of entries in the key-value store increases. CCF's implementation [54] of the key-value store uses a CHAMP map [58], whose access time grows logarithmically with the number of items.
Fig. 7: Transaction throughput/latency with different account numbers (f=1, dedicated cluster)

6.7 Checkpointing

We also explore the effect of checkpointing on performance. We vary the size of the key-value store and the checkpoint interval for the SmallBank workload. Fig. 6 shows the results as throughput vs. latency plots. As expected, the checkpoint overhead increases with the size of the key-value store and the checkpoint frequency, but the overhead is low for checkpoint intervals between 10 and 100K (approximately 1 to 10 minutes). The checkpoint interval impacts the overhead to check uPoMs at the enforcer. We expect checkpointing every 10 minutes to be acceptable in practice; it requires the enforcer to replay at most 10 minutes of transactions.

6.8 Overhead breakdown

To provide a permissioned ledger with individual account-ability, IA-CCF implements functionality that goes beyond traditional BFT consensus protocols, e.g., generating receipts. We now explore the impact of implementing this functionality on IA-CCF's throughput in the dedicated cluster.

We compare several variants of IA-CCF, each limiting functionality further: (a) IA-CCF; (b) IA-CCF-NoReceipt, i.e., without creating receipts; (c) without creating checkpoints; (d) with a small key-value store, i.e., the key-value store fits in the CPU cache; (e) without signed client requests; (f) using only MACs for message authentication between replicas; (g) without a ledger; and (h) with empty requests, i.e., without the overhead of executing transactions against the key-value store.

Tab. 3 shows that (a)–(d) have comparable throughput, but not verifying client signatures (e) doubles throughput. Only using MACs instead of signatures (f) or removing the ledger altogether (g) does not increase throughput substantially, but removing the overhead of executing transactions against the key-value store (h) again doubles throughput.

Tab. 3: Breakdown of IA-CCF features (f=1, dedicated cluster)

Variant	Throughput (tx/s)
(a) Full IA-CCF	47,841
(b) IA-CCF-NoReceipt	51,209
(c) + without checkpoints	51,288
(d) + small key-value store	53,759
(e) + without signed client requests	111,926
(f) + with MACs only	128,921
(g) + without ledger	131,959
(h) + with empty requests	299,321
HotStuff (with empty requests)	307,997
Pompē (with empty requests)	465,646

For context, we compare with two Byzantine consensus protocols with similar functionality to (h) above, HotStuff [62] and Pompē [66, 67]. HotStuff's throughput is 307,997 tx/s, but with higher latency (§6.2). By separating request ordering and consensus, Pompē achieves a throughput of 465,646 tx/s, also with worse latency (IA-CCF's 12 ms to Pompē's 73 ms). IA-CCF could utilize Pompē's techniques for increased throughput by sacrificing its two round-trip latency.

These breakdown results show that IA-CCF's overhead comes primarily from the cryptographic operations required for verifying client requests, followed by the transactional key-value store, rather than the consensus protocol or the mechanisms specific to providing individual accountability.

7   Related work

Permissioned ledgers. Many permissioned ledger systems [3, 4, 32, 52] rely on BFT consensus protocols to order transactions. Hyperledger Besu [32] and Quorum [52] use variants of PBFT [47, 55], which do not retain proof of a replica's operations, and therefore cannot assign blame. Diem [3] uses the DiemBFT [11] consensus protocol, which is based on HotStuff [62] and also lacks accountability features.

The IA-CCF prototype is built on top of CCF [54], an open source [44] distributed ledger framework deployed in the Azure cloud [43], which utilizes trusted execution environments (TEEs) [21, 35] to harden replicas. Russinovich et al. [54] describe CCF's programming model, receipts, governance, and replication protocols. CCF produces hardware attestation reports for the code running on each replica and adds them to the ledger. The ledger is signed by the CCF service and in the process binds CCF's public key to the code and hardware platform. While CCF enables auditing and can recover a ledger when all replicas crash, it relies on the security of TEEs, and its auditing does not guarantee individual accountability.

Byzantine consensus [17, 20, 37] distributes trust. Recent work on BFT protocols has focused on improving guarantees [5, 22, 46] or performance for particular use cases [57, 67]. SBFT [25] and HotStuff [62] scale to hundreds of replicas using threshold cryptography, which prevents blame assignment. For permissioned ledgers, scaling to many replicas without growing the consortium size does not improve trustworthiness, and consortia typically cannot grow arbitrarily.

Other work has explored misbehavior and its impact on Byzantine consensus. BFT2F [39] formalizes safety and liveness guarantees after more than f replicas are compromised. It provides PBFT's guarantees with up to f failures and provides *fork** consistency with up to $2f$ failures. For permissioned ledgers, *fork** consistency is not sufficient, because it is susceptible to double-spending attacks.

Depot [40] issues proofs-of-misbehavior after observing misbehavior, but it adopts eventual consistency, which is incompatible with permissioned ledgers. Pompē [67] prevents dishonest primaries from controlling the ordering of requests. It does not address scenarios in which there are more than f dishonest replicas though.

Accountability. PeerReview [27] ensures that distributed nodes remain accountable for their actions. As shown in §6.1, PeerReview incurs a high overhead when applied to a permissioned ledger. In contrast, IA-CCF introduces mechanisms specific to BFT state machine replication, such as a shared ledger with a Merkle tree, to improve both regular transaction execution and auditing.

Accountable virtual machines [26] carries out auditing through *spot checking* of checkpoints, but has the same performance overheads as PeerReview for ledgers. SNP [68] is a networking-specific implementation of accountability, offering provenance for routing decisions. Such specializations improve performance in particular domains, but are not directly applicable to permissioned ledgers.

BAR [1] and Prosecutor [65] incentivize replicas to act honestly by having honest replicas penalize misbehavior. This weaker model allows BAR to tolerate more than $1/3$ faulty replicas, while Prosecutor uses these incentives to improve performance. If these incentives fail [31], however, replicas share the blame.

Accountability with more than $f+1$ misbehaving replicas has been discussed before [14, 15, 28]. BFT Protocol Forensics [56] and Polygraph [19] propose a ledger auditing mechanism, but assume that fewer than $N-f$ replicas misbehave. They also do not support changing replica sets. ZLB [53] and Tendermint [14] support changes to the replica set but also assume that fewer than $N-f$ replicas misbehave.

8   Conclusions

In permissioned ledger systems, individual accountability is a strong disincentive for misbehavior. IA-CCF provides the evidence required to prove that $f+1$ or more replicas misbehaved when clients observe safety violations (even if all replicas fail). It offers strong consistency and security properties while providing state-of-the-art performance compared to existing ledger systems with weaker security guarantees. IA-CCF achieves this by integrating evidence collection for assigning blame with a novel ledger-based BFT consensus algorithm.

A Proof of L-PBFT linearizability

We present a correctness proof for L-PBFT. In particular, we show that *early execution* (Lemma 2) and the *nonce commitment* scheme (Lemma 3) are equivalent to their counterpart features in PBFT. In Thm. 1, we show linearizability of L-PBFT.

Lemma 1 (Rollback). *Any honest L-PBFT replica can roll back a suffix of the sequence of previously executed transaction batches.*

Proof. L-PBFT's state is distributed across several entities: a key-value store kv; a Merkle tree M; a ledger $\mathcal{L}$; a set of requests waiting to be ordered $\mathcal{T}$; a message store $\mathcal{M}$; and a nonce store $\mathcal{K}$. Therefore, to roll back a batch of transactions, it must be possible to roll back all of these entities.

Key-value store kv. The key-value store maintains a roll back transaction log. This enables transactions to be rolled back at a single transaction granularity. Thus, the last executed batch of transactions can be rolled back.

Merkle tree M. When a new node is added to L-PBFT's Merkle tree, it becomes the right-most leaf of the tree. The value of a node in the tree is never updated, and a node can only be deleted if it is the right-most node in the tree. Thus, during roll back, it is possible to remove the nodes from the right of the tree that represent the last batch of executed transactions (in reverse order).

Ledger $\mathcal{L}$. The ledger is represented by a file written to the disk by each replica. L-PBFT stores the index of all entries written to the ledger. To roll back the last executed batch, a L-PBFT replica truncates the ledger file to just before the first entry of the batch.

Transaction store $\mathcal{T}$. It is not necessary to undo changes to the transaction store. Transaction requests that are removed can be retransmitted by the client or other replicas if needed.

Message store $\mathcal{M}$, nonce store $\mathcal{K}$. All items in the transaction and nonce stores are indexed by sequence number and view. Since roll back occurs only during a view change, and each item is associated with a view, it is not necessary to modify the message and nonce stores, because honest replicas never send more than one item of a given type for the same sequence number and view.

Therefore, it is possible to roll back a suffix of the sequence of transaction batches executed by L-PBFT replicas. □

Lemma 2 (Early execution). *L-PBFT's early execution and PBFT execution agree on all committed transactions.*

Proof. In both PBFT and L-PBFT, the primary determines the order of request execution by ordering requests into batches and assigning numbers to batches in pre-prepare messages. In PBFT, requests are executed after commit and clients only accept results after transactions commit. In L-PBFT, requests are executed earlier, before the request even prepare, but the replicas only reply to clients after they prepare the requests and clients wait for matching replies from $N-f$ replicas. This ensures that they only obtain the transaction results after they commit as in PBFT.

As in PBFT, a faulty primary may cause requests for which pre-prepares are sent not to commit. L-PBFT deals with this case by rolling back early execution (see Lemma 1).
□

Lemma 3 (Nonce commitment). *The nonce commitment scheme is equivalent to replicas signing commit messages.*

Proof. L-PBFT, like PBFT, signs pre-prepare and prepare messages. Unlike PBFT, L-PBFT does not sign commit messages. Replicas sample a fresh random nonce for each pre-prepare or prepare message with sequence number s at view v, and add a hash of this nonce to the signed payloads. Later in the protocol, replicas include the nonce in the commit message, instead of an extra signature.

We show that this provides the same standard cryptographic security as the signature scheme (namely, resistance to existential forgery against chosen-message attacks) as long as the cryptographic hash function is second pre-image resistant on random inputs. Since the addition of a nonce to the signed payloads is injective, a forgery of a L-PBFT authenticator for a pre-prepare or prepare message yields a forgery against the signature scheme. A forgery of an authenticator for a commit message, i.e., a value with the same hash as a fresh random nonce that has not yet been revealed, is a second pre-image collision. □

Theorem 1. *L-PBFT is linearizable.*

Proof. L-PBFT changes the PBFT algorithm by adding early execution and the nonce commitment scheme. Lemmas 2 and 3 show that these preserve the behavior of PBFT.
□

B Proof of auditing correctness

First, we present the correctness proof for auditing without governance transactions and reconfiguration (§B.1). Then, we extend the proof to include governance transactions and reconfiguration (§B.2).

B.1 Correctness of auditing without reconfiguration

We begin with a description of terminology and notation. In §B.1.1 and Lemma 4, we then prove that, given a set of receipts, the auditor, with the help of the enforcer, can obtain a ledger package that is complete in relation to the receipts (or assign blame to $f+1$ misbehaving or slow replicas). A complete ledger package contains all evidence that is necessary for the auditor to assign blame to misbehaving replicas if the receipts reflect any linearizability violation. In §B.1.2 and Lemma 5, we show that, if a receipt does not appear correctly in a ledger package that is complete in relation to it, the auditor can assign blame to at least $f+1$ misbehaving replicas. In §B.1.3 and Lemma 6, using the previous lemmas, we first prove that the auditor can assign blame correctly if it is given a set of receipts that reflects a

serializability violation. Finally, Theorem 2 proves that, if a set of receipts reflects any linearizability violation, the auditor can assign blame to $f+1$ misbehaving or slow replicas.

Minimum ledger index. Each client transaction request includes a field that specifies the minimum ledger index that it can be executed at. Correct replicas do not order a transaction t at ledger index i, unless $i \geq m_i$ where m_i is the minimum index value of t. Correct clients set the minimum index of a transaction to at least M_i+1 where M_i is the largest value of the ledger index that they know of from the receipts that they have collected. The minimum index value is used to capture transaction dependencies efficiently and to reduce the amount of information that needs to be stored and transmitted to audit linearizability violations.

Ledger well-formedness and validity. A ledger fragment is *valid* if it can be produced by a sequence of correct primaries when there are at most f misbehaving replicas.

A ledger fragment is *well-formed* if either (i) it is valid, or (ii) it would be valid if not for the incorrect execution of one or more transactions, one or more incorrect checkpoint digests, or one or more invalid signatures or nonces.

A well-formed ledger matches the structural specifications of the L-PBFT protocol, i.e.,

- it specifies a serial ordering of transactions/entries, which respects their minimum ledger indices; and
- it includes evidence, and checkpoints at the required places.

A valid ledger is always well-formed, but a well-formed ledger can be invalid. A correct replica will never have a malformed ledger fragment, because replicas check the well-formedness of ledgers that they fetch. A correct replica may have an invalid ledger fragment. A ledger fragment can be well-formed but invalid only if there have at some point existed more than $N-f-1$ misbehaving replicas.

Notation. Given a receipt $\langle\langle t_j,i_j,o_j\rangle,x_j\rangle$, we denote $\langle t_j,i_j,o_j\rangle$ by tio_j. Unless explicitly defined otherwise, s_j refers to the sequence number in x_j of the receipt $\langle\text{tio}_j,x_j\rangle$.

We say that a replica has "signed a receipt" if its signature is recorded in the receipt in the pre-prepare/prepare signatures' fields (σ_p or in $\sum_s$).

Receipt validity. A receipt is *valid* if it is verifiable by Alg. 3.

Preparement evidence for a batch. The *preparement* evidence for a batch is $N-f$ signed pre-prepare/prepare messages for the batch, i.e., $\mathcal{P}$ in §3.

Checkpoint sequence numbers. Let $\langle\text{tio}_j,x_j\rangle$ be a valid receipt, d_{C_j} be the checkpoint digest in x_j, and C be the checkpoint interval. Anyone can calculate the sequence number at which the digest of the checkpoint is expected to be equal to d_{C_j} as follows: checkpoints are always taken at sequence numbers that are multiples of C and the digest in the receipt refers to the digest at the sequence number of the penultimate checkpoint transaction before s_j (except the first

C transactions, which have the digest at genesis). So given s_j, the sequence number with the corresponding checkpoint digest, s_{cp}, can be calculated as

$$s_{cp} = \begin{cases} 0 & \text{if } s_j < C \\ C(\lceil \frac{s_j}{C} \rceil - 2) & \text{otherwise.} \end{cases}$$

Note that the value of the digest itself is recorded in the last checkpoint transaction before s_j (except the first C transactions), i.e., the checkpoint transaction that follows the one at s_{cp}. That checkpoint transaction is at

$$\begin{cases} 0 & \text{if } s_j < C \\ s_{cp}+C & \text{otherwise.} \end{cases}$$

We assume that the genesis transaction gt is at sequence number 0.

Fetching checkpoints. Slow replicas can be brought up to date by fetching checkpoints and ledger fragments. When a correct replica fetches a checkpoint at sequence number s, it retrieves the ledger up to $s+C+P$. It first verifies the signatures in the evidence for the checkpoint transactions at s and $s+P$. Note that the replicas that signed the checkpoint transaction at s vouch for the validity of the ledger fragment between $s-C$ and s, whereas the replicas that signed the checkpoint transaction at $s+C$ vouch for the digest of the checkpoint at s.

A correct replica, then, verifies that the digest of the checkpoint that it fetched matches the value recorded at $s+C$. It also checks, for each checkpoint transaction at sequence number s' in the ledger, that the ledger's Merkle root at s' matches the root in the evidence for the transaction at s'. Finally, the replica replays the ledger fragment between $s+1$ and $s+C$.

As noted previously, a correct replica may have a well-formed ledger fragment that includes invalid signatures as replicas do not verify all signatures in the ledger fragments that they fetch. Therefore, when contacted for an audit, a correct replica never returns a ledger fragment that it fetched with a checkpoint at sequence number s, without including the checkpoint transaction at $s+C$ and the evidence for that transaction.

B.1.1 Obtaining the ledger

Ledger package. A *ledger package* from a replica consists of one to four components:

1. a ledger fragment $\mathcal{F}$ that contains entries that locally prepared at the replica;
2. an optional *suffix* $\mathcal{U}$ that contains entries that were preprepared atomically after a view-change but not yet prepared at the replica;
3. an optional *message box* $\mathcal{E}$ that contains some of the messages from the replica's message box $\mathcal{M}$; and
4. an optional *checkpoint cp*.

Complete ledger package. Let $\mathcal{R}$ be a set of valid receipts; s_{max} be the maximum sequence number in $\mathcal{R}$; s_{min} be the sequence number of the checkpoint whose digest is expected to equal the checkpoint digest in the receipt with the smallest sequence number in $\mathcal{R}$ (s_{min} can be calculated as described in the previous section); v_{min} and v_{max} be the minimum and maximum view numbers in the receipts in $\mathcal{R}$, respectively.

A ledger package is *complete* in relation to $\mathcal{R}$ if all of the following are true:

- $\mathcal{F} + \mathcal{U}$ is well-formed;
- if $s_{min} = 0$, cp contains the checkpoint at genesis (empty); otherwise, the digest of cp is equal to the one in the second checkpoint transaction in $\mathcal{F} + \mathcal{U}$;
- $\mathcal{F}$ includes at least one set of *view-change* and *new-view* messages for a view less than or equal to $v_{min} + 1$ (v_{min} requirement), and one set of *view-change* and *new-view* messages for a view greater than or equal to v_{max} (v_{max} requirement);
- All signatures in $\mathcal{F} + \mathcal{U}$ and $\mathcal{E}$ are valid.

and one of the following is true:

- $\mathcal{F}$ includes entries between s_{min} and $s_{max} + P$;
- $\mathcal{F}$ includes entries between s_{min} and $s_{max} + c$ where $c \in [0, P)$. $\mathcal{E}$ contains $P - c$ valid preparement evidence for entries from $s_{max} - c$ to s_{max}; or
- $\mathcal{F}$ includes entries between s_{min} and $e = \max(s_{min}, s_{max} - c)$ where $c \in [1, P]$. $\mathcal{E}$ contains valid preparement evidence for entries from $\max(s_{min}, e - P)$ to e. The suffix $\mathcal{U}$ contains entries between $e + 1$ and s_{max} that are preprepared but not prepared in some view $v' \geq v_{max}$ and $\mathcal{E}$ contains preparement evidence from a view $< v'$ for entries between $e + 1$ and s_{max}.

Lemma 4 (Obtaining a complete ledger package). *Given a set of valid receipts $\mathcal{R}$, an auditor can either obtain a ledger package that is complete in relation to $\mathcal{R}$, or assign blame to at least $f + 1$ misbehaving or slow replicas.*

Proof. Select from the receipts in $\mathcal{R}$, the receipts with the highest view number v_{max}. Then, from those receipts select the receipts with the highest sequence number. Finally, among those, let R_{vmax} be the receipt with the highest index number. (We assume there is no tie; otherwise, the auditor assigns blame to the replicas that signed both tied receipts.)

The enforcer asks all replicas that signed R_{vmax} for a ledger package that is complete in relation to $\mathcal{R}$. We assume that correct replicas or members respond to the enforcer before the agreed deadline. Once the enforcer has responses from $f + 1$ replicas, it relays the responses to the auditor; otherwise at the deadline, the enforcer assigns blame to at least $f + 1$ misbehaving or slow replicas.

We show that a correct replica can either respond with: a ledger package that is complete in relation to $\mathcal{R}$ or a ledger package with which the auditor can assign blame to $f + 1$ misbehaving replicas. Therefore, after checking $f + 1$ responses, the auditor either finds a complete ledger package, or assigns blame to $f + 1$ misbehaving replicas.

Note that a correct replica that is contacted by the enforcer can always satisfy the first three conditions of completeness: (1) correct replicas always maintain well-formed ledgers and they record/can recalculate checkpoints; (2) the v_{min} requirement can always trivially be satisfied by including the set of *view-change* and *new-view* messages for view 0 in $\mathcal{F}$. In practice, for efficiency, correct replicas would satisfy this requirement by including the set of *view-change* and *new-view* messages for some view v', where v' is the latest possible in $[0, v_{min} + 1]$; and (3) since the replicas that are asked are the replicas that signed R_{vmax}, they must have *view-change* and *new-view* messages for view v_{max}. Therefore, any replica that returns a ledger package that violates any of the first three conditions can be assigned blame.

The fourth condition of completeness requires that all signatures and the matching nonces in the ledger package are correct. Let $\langle \mathcal{F}, \mathcal{U}, \mathcal{E}, cp \rangle$ be a ledger package returned by a replica. If $\mathcal{U}$ or $\mathcal{E}$ contains a message or transaction with an invalid signature, the auditor can assign blame to the replica. $\mathcal{E}$ contains messages from the replica's message box and $\mathcal{U}$ contains batches that pre-prepared at the replica. A correct replica never considers a message or pre-prepares a batch that includes an invalid signature. Otherwise, let s_w be a sequence number where there is a transaction or message with an invalid signature. The auditor can look for the first checkpoint transaction that follows s_w that has no invalid signatures in its evidence. If one exists, the auditor can assing blame to all $N - f$ replicas that signed that checkpoint transaction. If no such checkpoint transaction exists, the auditor can assign blame to the responding replica, since a correct replica never returns a ledger fragment that it has fetched with a checkpoint without including the committed checkpoint transaction that records that checkpoint's digest. So given a ledger package from a replica, the auditor can always verify all signatures and nonces in the package or assign blame to the responding replica or $N - f$ misbehaving replicas. So below, for brevity, we can assume that the ledger package that a replica returns has no invalid signatures or nonces.

Additionally, for a correct replica that is contacted by the enforcer, one of the following must hold:

- **The correct replica has locally prepared entries up to at least s_{max}:** In this case, the replica can form a complete ledger package that includes either:
    - (i) a well-formed ledger fragment $\mathcal{F}$ that contains entries from s_{min} to $s_{max} + P$; or
    - (ii) a well-formed $\mathcal{F}$ that contains entries from s_{min} to $s_{max} + c$ where $c \in [0, P)$, and $\mathcal{E}$ that contains $P - c$ valid preparement evidence for entries from $s_{max} - c$ to s_{max}.

- **The correct replica has not locally prepared entries up to $s_{\max}$ and it has locally prepared entries up to $e = s_{\max} - c$ where $c \geq 1$:** In this case, (1) a correct replica can include entries between $s_{\min}$ and e in a well-formed ledger fragment $\mathcal{F}$, and it can include the necessary preparement evidence in $\mathcal{E}$ (if $s_{\min} \leq e$); and (2) if the replica has any batches that it has preprepared but not prepared due to a view-change, it can include the related *view-change* and *new-view* messages in $\mathcal{F}$ and the batches in $\mathcal{U}$. Let p be the last sequence number for which there is a batch in $\mathcal{F} + \mathcal{U}$. If $p > e$, the correct replica can include the preparement evidence for entries between $e+1$ and p in $\mathcal{E}$ as well. A correct replica can form a ledger package as described above. If $p \geq s_{\max}$, the ledger package is complete, and the replica can return it. Otherwise, $p < s_{\max}$. Let $R_{s_{\max}}$ be the receipt in $\mathcal{R}$ with the largest sequence number $s_{\max}$ and let $v_{s_{\max}}$ be the view number in $R_{s_{\max}}$. Note that $v_{s_{\max}} \leq v_{\max}$ by definition, and in the correct replicas' ledger, there must exist at least one set of *view-change* and *new-view* messages for a view $v' > v_{s_{\max}}$ such that none of the *view-change* messages include a pre-prepare message for any batch at $s_{\max}$. The correct replica can return a ledger package that contains these *view-change* and *new-view* messages. The auditor can use the returned ledger package to assign blame to the intersection of replicas that signed $R_{s_{\max}}$ and that sent the set of *view-change* messages for v', as these replicas have prepared a batch at $s_{\max}$ but did not report it during the view change.

Thus, for each of the $f+1$ responses, either the response is complete in relation to $\mathcal{R}$, or the auditor can assign blame to the misbehaving responder, or at least $f+1$ misbehaving replicas. □

By definition of completeness, if a ledger package is complete in relation to a set of valid receipts $\mathcal{R}$, it is complete in relation to any subset of $\mathcal{R}$.

Finding preparement evidence. For a batch at s_r, the auditor can find the preparement evidence for the batch as follows:

- if $\mathcal{F}$ contains an entry at $s_r + P$, it is collected from there;
- if $\mathcal{F}$ contains the entry at s_r but not at $s_r + P$, it is collected from $\mathcal{E}$; and
- if $\mathcal{F}$ does not contain an entry at s_r but $\mathcal{U}$ contains an entry at s_r, it is also collected from $\mathcal{E}$, albeit it is for the same batch from a prior view.

B.1.2 Incompatibility

Let $R = \langle \text{tio}_r, x_r \rangle$ be a valid receipt at sequence number s_r. Let $\langle \mathcal{F}, \mathcal{U}, \mathcal{E}, cp \rangle$ be a ledger package that is complete in relation to R. Let B_l be the batch that is at s_r in $\mathcal{F} + \mathcal{U}$. R is *incompatible* with B_l if any of the following hold:

- t_r does not appear in B_l;
- it does not appear in the i_rth position; or
- o_r is different.

Lemma 5 (Receipt-ledger incompatibility). *Let $R = \langle \text{tio}_r, x_r \rangle$ be a valid transaction receipt for sequence number s_r. Let $\langle \mathcal{F}, \mathcal{U}, \mathcal{E}, cp \rangle$ be a ledger package that is complete in relation to R. Let B_l be the batch in the package at s_r. If R is incompatible with B_l, the auditor can assign blame to at least $f+1$ misbehaving replicas.*

Proof. The auditor can calculate the set of replicas that signed B_l using the preparement evidence that can be found as described above. These replicas are called $\mathcal{E}_l$.

Let $\mathcal{E}_r$ be the set of replicas that have signed the receipt. Let v_r be the view number in the receipt and v_l be the view number in the preparement evidence of B_l.

- $v_r = v_l$: Correct replicas never sign pre-prepare or prepare messages for different batches in the same view. Therefore, the auditor can assign blame to the replicas in the intersection of $\mathcal{E}_r$ and $\mathcal{E}_l$, and $|\mathcal{E}_r \cap \mathcal{E}_l| \geq f+1$.
- $v_l > v_r$: Correct replicas include the pre-prepare messages for the last P prepared batches in their *view-change* messages until the batches commit or a different batch is prepared at the sequence number. A correct primary always re-preprepares the latest batch that it finds in the set of $N - f$ *view-change* messages that it receives. Thus, there exists at least one view $v_c \in [v_r + 1, v_l]$ where zero of the $N - f$ *view-change* messages for v_c contain a pre-prepare message for the batch at sequence number s_r that is referenced in R. The ledger package is complete in relation to R, so $\mathcal{F}$ includes at least one set of *view-change* and *new-view* messages for a view less than or equal to $v_r + 1$ (the $v_{\min}$ requirement). It must also include the set of *view-change* and *new-view* messages for v_c as $v_l \geq v_c \geq v_r + 1$.
  Let $\mathcal{E}_c$ be the set of replicas that have sent the *view-change* messages to the primary for view v_c. The auditor can assign blame to the replicas that are in the intersection of $\mathcal{E}_r$ and $\mathcal{E}_c$ and $|\mathcal{E}_r \cap \mathcal{E}_c| \geq f+1$.
- $v_l < v_r$: There exists at least one view $v_c \in [v_l + 1, v_r]$ where zero of the $N - f$ *view-change* messages for v_c contains a pre-prepare message for the batch at sequence number s_r that is referenced in R. The ledger package is complete in relation to R so $\mathcal{F}$ includes at least one set of *view-change* and *new-view* messages for a view greater than or equal to v_r, so it must include the set of *view-change* and *new-view* messages for v_c as $v_l + 1 \leq v_c \leq v_r$ (the $v_{\max}$ requirement). Similar to previous case afterwards.

□

B.1.3 Violations

Ordering receipts. Given a set of valid receipts, the auditor can order them lexicographically based on the corresponding (sequence number, index number, view number) tuples. (We can assume that there is no tie; otherwise, the auditor assigns blame to the replicas that signed both tied receipts.) We say that a receipt R_1 is *earlier/later* than a receipt R_2, if it

is ordered before/after R_2 with this scheme, respectively. For example, the earliest receipt in a set of valid receipts is the one with the lowest view number, among those with the lowest index number, among those with the lowest sequence number.

Lemma 6 (Serializability violations). *Let $\mathcal{R} = \{(tio_0, x_0), ..., (tio_k, x_k))\}$ be a set of valid receipts that violates serializability. Then, the auditor can assign blame to at least $f+1$ misbehaving or slow replicas.*

Proof. First, the auditor can obtain a ledger package $\langle \mathcal{F}, \mathcal{U}, cp, \mathcal{E} \rangle$ that is complete in relation to $\mathcal{R}$; otherwise, it can assign blame to at least $f+1$ misbehaving or slow replicas by Lemma 4. Note that, as the ledger package is complete in relation to $\mathcal{R}$, it is complete in relation to any receipt $R_j \in \mathcal{R}$.

Since the receipts in $\mathcal{R}$ violate serializability, no serial execution of $t_0, ..., t_k$ can produce $io_0, ..., io_k$. $\mathcal{F} + \mathcal{U}$ is well-formed, so there are two options for its validity:

Valid ledger. $\mathcal{F} + \mathcal{U}$ is a valid ledger, so every transaction in it is ordered and executed serially. However, the receipts in $\mathcal{R}$ violate serializability. Therefore, there must exist at least one receipt $\langle tio_w, x_w \rangle \in R$ that is incompatible with the batch at s_w in $\mathcal{F} + \mathcal{U}$. By Lemma 5, the auditor can assign blame to at least $f+1$ misbehaving replicas.

Invalid ledger. $\mathcal{F} + \mathcal{U}$ is a well-formed but invalid ledger. So there exists at least one transaction t_w (which does not have to be in $\mathcal{R}$) that was executed incorrectly in some batch s_w, or one checkpoint that was created incorrectly.

The auditor can order $\mathcal{R}$ as described above. Let R_e be the earliest receipt in $\mathcal{R}$. Let d_{C_0} be the checkpoint digest in R_e. Let s_{C_0} be the sequence number with the expected checkpoint digest d_{C_0}, calculated by the auditor using s_e and the checkpoint interval C as previously described. If $s_{C_O} = 0$, but the digest in R_e is not equal to the digest in the genesis transaction, the auditor can assign blame to all replicas that signed R_e. Otherwise, the ledger package is complete with respect to R_e, and $\mathcal{F} + \mathcal{U}$ is thus well-formed, so: (i) the entry at s_{C_0} in $\mathcal{F} + \mathcal{U}$ is a checkpoint transaction; and (ii) the checkpoint transaction in $s_{C_O} + C$ exists as $s_{C_0} < s_{C_O} + C < s_e$ and contains the digest of cp. If the digest of cp in the ledger package is not d_{C_0}, the auditor can assign blame to the replicas that signed both the checkpoint transaction at $s_{C_O} + C$ and R_e. The digest in that checkpoint transaction is for the previous checkpoint and the batches before the previous checkpoint have already committed since $C > P$.

Otherwise, the auditor replays the ledger starting from the checkpoint transaction at s_{C_0}, creating checkpoints at checkpoint sequence numbers. Doing so, the auditor either obtains $\langle t_w, i_w, o_a \rangle \neq \langle t_w, i_w, o_w \rangle$ or finds that an incorrect checkpoint digest is recorded at s_w. In either case, the auditor can assign blame to all replicas that signed for the batch at s_w. $\square$

Theorem 2 (Linearizability violations). *Let $\mathcal{R}$ be a set of receipts that violate linearizability. Then, the auditor can*

assign blame to at least $f+1$ misbehaving or slow replicas.

Proof. If the receipts also violate serializability, the auditor can assign blame to at least $f + 1$ misbehaving or slow replicas by Lemma 6.

Otherwise, since the receipts violate linearizability but not serializability, the ordering of the transactions in $\mathcal{R}$ must violate the real-time ordering of the transactions. So there exists at least two transactions, t_a and t_b, in $\mathcal{R}$ such that the receipt for tio_a was received by the client before t_b was sent, but $i_a \geq i_b$. t_b was sent after $\langle tio_a, x_a \rangle$ was received, so a correct client sets the minimum index l of tio_b to at least $i_a + 1$. Since $i_b \leq i_a$, the auditor can assign blame to all replicas who have sent the receipt for tio_b. $\square$

B.2 Correctness of auditing with reconfiguration

In this section, we first summarize how reconfiguration happens, introduce new terminology, and update prior terminology. Then, in Lemma 7, we prove that, if the auditor detects a fork in governance, it can assign blame to $f+1$ misbehaving replicas. In §B.2.1, we update the prior discussion on obtaining a complete ledger package. In §B.2.2 and Lemma 9, we prove that, if a receipt and the corresponding batch in a ledger package are prepared in different configurations, the auditor can assign blame to $f + 1$ misbehaving replicas. In §B.2.3, using Lemma 9, we update the prior lemma about incompatibility. Finally, §B.2.4 updates the prior proofs on violations, and in Theorem 3, we prove the correctness of auditing in the complete IA-CCF ledger system.

Summary of reconfiguration. A correct primary ends the batch it is working on once it executes a governance transaction. Therefore, each batch includes at most one governance transaction and i_g in a receipt refers to the last governance transaction executed before the transaction in the receipt. The final vote transaction that is necessary to pass a referendum triggers the configuration change. $2P$ *end-of-config* batches follow the final vote before the configuration change. The governance sub-ledger consists of batches and evidence for all governance transactions. It also includes, for each configuration, the P^{th} and $2P^{\text{th}}$ *end-of-config* batches, which commit the final vote transaction that triggers reconfiguration and the P^{th} *end-of-config* batch respectively. The P^{th} *end-of-config* batch links to the final vote transaction, because its pre-prepare message includes the Merkle root of the batch that includes the final vote transaction.

Updates to well-formedness and validity. A ledger fragment is *valid* if it can be produced by a sequence of correct primaries in a sequence of configurations where in each configuration there are at most f failures.

In addition to the previous structural specifications, governance changes are serialized and include the required *end-of-config* and *start-of-config* messages.

Note that correct replicas check the validity of the governance sub-ledger fragments that they fetch, so their

governance sub-ledgers are valid, in addition to well-formed.

Configuration number. The configuration number of a configuration C is the distance that it is from the configuration at the genesis. The genesis has configuration number 0. A configuration that follows the genesis configuration has number 1 and so on.

Supporting governance chain of a receipt. Every receipt R includes the index of the latest governance transaction. A correct client makes sure that it has a matching chain of valid governance transaction receipts for each receipt that it has. This includes the receipts for all governance transactions from the genesis up to the latest governance transaction, and the receipt for the P^{th} *end-of-config* batch for each configuration change. The supporting governance chain of a receipt R is the sequence of governance-related receipts that starts from the genesis transaction receipt and ends with the P^{th} *end-of-config* batch receipt before the configuration that signed R takes effect.

A supporting governance chain of a receipt matches a governance sub-ledger if each receipt in the chain is compatible with the governance sub-ledger. (For *end-of-config* batches, compatibility considers committed Merkle roots as well.) Similarly, a supporting governance chain can be a prefix of a governance sub-ledger.

Updates to receipt validity. A receipt is *valid* if it is verifiable by Alg. 3, and it is attached a valid supporting governance chain.

Updates to calculating checkpoint sequence numbers. If a sequence number that is multiple of the checkpoint interval C falls into an *end-of-config/start-of-config* sequence, checkpointing is skipped. A checkpoint is taken at the beginning of each new configuration, and the digest of the first checkpoint in a configuration is included in the first checkpoint transaction, as opposed to the one that follows (this is similar to genesis).

Let $\langle tio_j, x_j \rangle$ be a valid receipt and s_{fv} be sequence number of the final vote transaction for the last configuration change in the supporting governance chain of the receipt. The first checkpoint of the configuration that prepared the receipt is expected at $s_{fcp} = s_{fv} + 2P + 1$. (Except the genesis configuration, for which $s_{fcp} = 0$.)

So given s_j, the sequence number s_{cp} of the checkpoint whose digest is in x_j can be calculated with

$$s_{cp} = \begin{cases} s_{fcp} & \text{if } s_j < s_{fcp} + C \\ C\left(\left\lceil \frac{s_j - s_{fcp}}{C} \right\rceil - 2\right) & \text{otherwise.} \end{cases}$$

Updates to fetching checkpoints. Following a configuration change, a correct new replica fetches the checkpoint at the penultimate checkpoint sequence number s' in the previous configuration (or the first checkpoint sequence number if there is only one). It also retrieves the full ledger. It

replays the ledger from s' before creating a checkpoint at the beginning of the configuration.

Equivalence of P^{th} *end-of-config* batches. Two P^{th} *end-of-config* batches are equivalent if they:

(i) are at the same index and sequence number; and
(ii) are preceded by the same valid governance sub-ledger (their pre-prepares include the same committed Merkle root).

Two receipts for P^{th} *end-of-config* batches are equivalent if the batches specified in them are equivalent.

Governance fork. There is a fork in governance if there is a fork in the governance sub-ledger. That is, there are at least two P^{th} *end-of-config* batches for the same configuration number that belong in valid governance sub-ledgers, but that are not equivalent.

We say that there is a fork between two valid supporting governance chains if there are receipts for two P^{th} *end-of-config* batches for the same configuration number that are not equivalent.

We say that there is a fork between a valid supporting governance chain and a valid governance sub-ledger, if for the same configuration number, the P^{th} *end-of-config* batch specified by the receipt in the chain is not equivalent to the P^{th} *end-of-config* batch in the sub-ledger.

Lemma 7 (Governance fork). *If there is a fork in governance, the auditor can assign blame to at least $f + 1$ misbehaving replicas.*

Proof. If there is a fork in governance, there are at least two P^{th} *end-of-config* batches for the same configuration number that are not equivalent, namely P_1 and P_2.

A correct replica only prepares a P^{th} *end-of-config* batch at sequence number s once the final vote transaction that passes the referendum is committed at sequence number $s - P$. Thus, all governance transactions preceding it are committed too. This final vote transaction triggers the configuration change.

So the auditor can assign blame to the replicas that prepared both P_1 and P_2, because a correct replica that prepares one will never prepare another non-equivalent P^{th} *end-of-config* batch in the same configuration number. $\square$

Longest supporting governance chain. Let $\mathcal{R}$ be a set of valid receipts. If there is a fork between the supporting governance chains of the receipts in $\mathcal{R}$, the auditor can assign blame to at least $f + 1$ misbehaving replicas by Lemma 7. So the auditor can always obtain a *longest supporting governance chain* for the receipts in $\mathcal{R}$. This chain is the union of all supporting chains for receipts in $\mathcal{R}$.

Onwards, we assume that, given any set of valid receipts, the supporting governance chains are fork-free with each other and that there is a longest supporting governance chain;

otherwise, the auditor can assign blame to $f+1$ misbehaving replicas by Lemma 7.

Transaction receipts. Onwards, we assume that a receipt is for a transaction and not for *end-of-config/start-of-config* batches. If the receipts for *end-of-config/start-of-config* indicate a fork in governance, misbehaving replicas can be blamed using Lemma 7; otherwise, the *end-of-config/start-of-config* batches do not have any usage and do not affect the key-value store, so do not affect linearizability.

B.2.1 Updates to obtaining the ledger

Updated ledger package. A ledger package includes an additional required field:

- the committed governance sub-ledger $\mathcal{N}$ of the replica.

Updated definition of completeness. Let $\mathcal{R}$ be a set of valid receipts. Define $s_{max}, v_{min}, v_{max}$ as previously. Calculate s_{min} using the receipt with the smallest configuration number, among those with the smallest sequence number in $\mathcal{R}$. Let n_{gmax} be the longest supporting governance chain in $\mathcal{R}$.

A ledger package is *complete* in relation to $\mathcal{R}$ if, in addition to the prior conditions about well-formedness, length, and v_{min}/v_{max} requirements:

- n_{gmax} is a prefix of $\mathcal{N}$ (i.e. the package is obtained from a replica in a configuration which is equal to or succeeds all configurations in $\mathcal{R}$);
- $\mathcal{N}$ is valid; and
- $\mathcal{N}$ matches $\mathcal{F}$.

  The condition for the checkpoint cp is updated as follows:

- if s_{min} is calculated as the first checkpoint transaction in a configuration (or zero), the digest of cp is equal to the one in the checkpoint transaction at s_{min}; otherwise, the digest of cp is equal to the one in the second checkpoint transaction in $\mathcal{F} + \mathcal{U}$.

Lemma 8 (Obtaining a complete ledger package with reconfiguration). *Given a set of valid receipts $\mathcal{R}$, an auditor can either obtain a ledger package that is complete in relation to $\mathcal{R}$, or assign blame to at least $f+1$ misbehaving or slow replicas.*

Proof. As mentioned before, we assume that there is no fork between the supporting governance chains of the receipts in $\mathcal{R}$. Let R_{gmax} be the receipt with the highest index number, among those with the highest sequence number, among those with the highest view number, among those with the longest supporting governance chain in $\mathcal{R}$. Let n_{gmax} be the supporting governance chain of R_{gmax}.

We assume that there is a reliable mechanism to look up the most recent system configuration. Using this mechanism, the auditor looks up the most recent committed governance sub-ledger and the set of replicas that signed the first checkpoint transaction of the most recent configuration. If there is a fork

between n_{gmax} and the governance sub-ledger that is looked-up, the auditor can assign blame to at least $f+1$ misbehaving replicas by Lemma 7; otherwise, the auditor checks whether the sub-ledger that is looked up is longer than n_{gmax}. If so, the enforcer asks all the replicas that signed the first checkpoint transaction of the most recent configuration for a ledger package; otherwise, the replicas that have signed R_{gmax} are asked.

As in Lemma 4, the enforcer asks replicas for a ledger package that is complete in relation to $\mathcal{R}$. At the deadline, the enforcer relays the responses to the auditor. There are at least $f+1$ responses, or the enforcer can assign blame to $f+1$ misbehaving or slow replicas.

As before, we show that a correct replica can either respond with: a ledger package that is complete in relation to $\mathcal{R}$, or a ledger package with which the auditor can assign blame to $f+1$ misbehaving replicas.

First, note that a correct replica that is contacted by the enforcer can always satisfy the updated completeness conditions (related to $\mathcal{N}$), because the replica is part of the most recent configuration and the conditions all pertain to keeping a valid governance sub-ledger. Of the conditions described previously, the well-formedness and v_{min} conditions can be satisfied, and invalid signatures in the package can be handled, just as in Lemma 4. Since the replicas that are asked are not necessarily the replicas that signed the receipt with the highest view in $\mathcal{R}$, it is possible that they cannot satisfy the v_{max} requirement even if they are correct.

So, for a correct replica that is contacted by the enforcer one of the following must hold:

- **The replica cannot satisfy the v_{max} requirement:** Let R_{vmax} be the latest receipt when the receipts are ordered lexycographically by (view number, configuration number, sequence number, index number). Let n_{vmax} be the supporting governance chain of R_{vmax}. If there is a fork between n_{vmax} and the committed sub-ledger $\mathcal{N}$ of the replica, the replica can return its governance sub-ledger and the auditor can assign blame to at least $f+1$ misbehaving replicas by Lemma 7. Otherwise, n_{vmax} must be a prefix of $\mathcal{N}$ since the enforcer asks replicas from the most recent configuration. There are two possibilities for the relationship between n_{vmax} and $\mathcal{N}$:

  1. $\mathcal{N} = n_{vmax}$. So $R_{gmax} = R_{vmax}$. Therefore, the correct replica signed R_{vmax}. Any correct replica that signed R_{vmax} has the *view-change* and *new-view* messages for v_{max}, so this case is a contradiction.
  2. $\mathcal{N}$ is longer than n_{vmax}. Let P_{vmax+1} be the P^{th} *end-of-config* batch that ends R_{vmax}'s configuration C. Since the replica is correct and cannot satisfy the v_{max} requirement, P_{vmax+1} must be prepared in a view $< v_{max}$. Any correct replica that prepared P_{vmax+1} must have committed a final vote transaction that triggers the configuration change in their ledger in a view less than v_{max}. Since correct replicas never reset their ledger by

more than P sequence numbers, they do not pre-prepare any batch with view $v_{\max}$ in C. So, the auditor can assign blame to the intersection of replicas that signed $R_{v\max}$ and prepared $P_{v\max+1}$.

- **The replica can satisfy the $v_{\max}$ requirement:** If, additionally, the replica has prepared (or pre-prepared with view changes) batches up to at least $s_{\max}$, it can return a ledger package that is complete in relation to $\mathcal{R}$ just as in Lemma 4.

  Otherwise, let $R_{s\max}$ be the receipt with the largest sequence number $s_{\max}$. Let $n_{s\max}$ be the supporting governance chain of $R_{s\max}$. If there is a fork between $n_{s\max}$ and the replica's $\mathcal{N}$, the replica can return $\mathcal{N}$ and the auditor can assign blame to at least $f+1$ misbehaving replicas by Lemma 7. Otherwise, $n_{s\max}$ must be a prefix of $\mathcal{N}$ since the replicas asked by the enforcer are from the most recent configuration. Again, there are two possibilities:

  1. $\mathcal{N}$ **is longer than** $n_{s\max}$**:** Let $P_{s\max+1}$ be the P^{th} *end-of-config* batch that ends $R_{s\max}$'s configuration. Since the replica is correct and cannot satisfy the $s_{\max}$ requirement, $P_{s\max+1}$ must be prepared at a sequence number less than $s_{\max}$. Any correct replica that prepared $P_{s\max+1}$ must have committed a final vote transaction that triggers the configuration change at latest at sequence number $s_{\max} - (P + 1)$. Since a correct replica never resets its ledger by more than P sequence numbers, the auditor can assign blame to the replicas that signed both $R_{s\max}$ and prepared $P_{s\max+1}$.
  2. $\mathcal{N} = n_{s\max}$**:** The group of replicas asked by the enforcer are from the same configuration that signed $R_{s\max}$, which is the most recent configuration. Since the replica is correct and from the most recent configuration $v_{s\max} \le v_{\max}$ by definition. In $\mathcal{F}$, as before, there must exist at least one set of *view-change* and *new-view* messages for a view $v' > v_{s\max}$ such that none of the *view-change* messages includes a pre-prepare for any batch at $s_{\max}$. Note that the configuration of the replicas that have sent these *view-change* messages must be the same as the configuration that signed the receipt, as that is the most recent configuration in the system. So just as in Lemma 4, the auditor can assign blame to the replicas that signed both $R_{s\max}$ and that sent the set of *view-change* messages for v'.

So, for each of the $f+1$ responses, either the response is complete in relation to $\mathcal{R}$, or the auditor can assign blame to the responder, or at least $f+1$ misbehaving replicas. □

B.2.2 Mismatching configurations

Lemma 9 (Receipt-ledger configuration mismatch)**.** *Let* $R = \langle tio_r, x_r \rangle$ *be a valid receipt that was produced in a configuration* C_r*. Let* B_l *be the batch that is at* s_r *in a ledger package that is complete in relation to R. Let* C_l *be the config-*

uration of the replicas that signed B_l. If $C_r \ne C_l$, the auditor can assign blame to at least $f+1$ misbehaving replicas.

Proof. Since R is a valid receipt, it has a valid supporting governance chain. Since the ledger package is complete, it includes a valid governance sub-ledger $\mathcal{N}$ that leads to C_l, which is fork-free with the supporting governance chain of R. One of the following must hold:

- $C_r < C_l$**:** C_r **precedes** C_l**:** Let P_{r+1} be the P^{th} *end-of-config* batch that ends the configuration C_r. This batch and its evidence is included in $\mathcal{N}$. Since the package is complete, $\mathcal{N}$ is consistent with the ledger fragment in the package. Since that ledger fragment is well-formed and B_l is at s_r, P_{r+1} is at the latest at sequence number $s_r - (P+1)$. Any replica that prepared P_{r+1} must have committed a final vote transaction that triggers the configuration change at the latest at sequence number $s_r - (2P+1)$. A correct replica that has prepared a batch at s_r in C_r never resets its ledger to earlier than $s_r - P$ even with view changes. So the auditor can assign blame to the replicas that both prepared P_{r+1} and signed R.
- $C_r > C_l$**:** C_r **succeeds** C_l**:** We show that this case is impossible given that R is valid, and there is no fork between its supporting governance chain and $\mathcal{N}$. Since the ledger package is complete in relation to R, $\mathcal{N}$ includes the P^{th} *end-of-config* batch leading to C_r and it matches the well-formed ledger fragment in the package. Since B_l is at s_r, that batch can at earliest be at sequence number $s_r + P$. So there cannot be a valid receipt produced in C_r at s_r.

□

B.2.3 Updates to incompatibility

Lemma 10 (Receipt-ledger incompatibility with reconfiguration)**.** *Let* $R = \langle tio_r, x_r \rangle$ *be a valid transaction receipt at sequence number* s_r*. Let* $\langle \mathcal{F}, \mathcal{U}, \mathcal{E}, cp, \mathcal{N} \rangle$ *be a ledger package that is complete in relation to R. Let* B_l *be the batch in the package at* s_r*. If R is incompatible with* B_l*, the auditor can assign blame to at least* $f+1$ *misbehaving replicas.*

Proof. Define $\mathcal{E}_l, \mathcal{E}_r, v_l, v_r$ as in Lemma 5. Note that we can assume that both the receipt and B_l are prepared by the same configuration C; if not, the auditor can assign blame to $f+1$ misbehaving replicas by Lemma 9.

- $v_r = v_l$**:** Same as Lemma 5.
- $v_l > v_r$**:** Calculate $\mathcal{E}_c$ as described in Lemma 5. If the replicas in $\mathcal{E}_c$ are also from the configuration C, the auditor can assign blame just as in Lemma 5; otherwise, if the replicas in $\mathcal{E}_c$ are from a preceding configuration, the first checkpoint transaction of C is at the latest at sequence number $s_r - (P+1)$ since B_l is prepared by C and $\mathcal{F} + \mathcal{U}$ is well-formed. Furthermore, that checkpoint transaction is prepared in a view $v' > v_r$. A correct replica never signs the receipt at s_r in a view v_r and then resets its ledger by more than P sequence numbers while view changing to v'.

So, the auditor can assign blame to the replicas that signed both that checkpoint transaction and the receipt.

- $v_l < v_r$: Calculate $\mathcal{E}_c$ as described in Lemma 5. If the replicas in $\mathcal{E}_c$ are also from the configuration $\mathcal{C}$, the auditor can assign blame just as in Lemma 5; otherwise the replicas in $\mathcal{E}_c$ are from a configuration that succeeds $\mathcal{C}$. In this case, the P^{th} *end-of-config* batch that ends the configuration $\mathcal{C}$ is at the earliest at sequence number $s_r + P$, since B_l is prepared by $\mathcal{C}$ and $\mathcal{F} + \mathcal{U}$ is well-formed. Furthermore, that batch is prepared in a view $v' < v_r$. A correct replica that prepares that P^{th} *end-of-config* batch commits to the configuration change; it never resets its ledger to earlier than s_r and signs R. So, the auditor can assign blame to the replicas that signed both that *end-of-config* batch and the receipt.

$\square$

B.2.4 Updates to violations

Lemma 11 (Serializability violations with reconfiguration).
Let $\mathcal{R} = \{(tio_0, x_0), ..., (tio_k, x_k))\}$ be a set of receipts that violates serializability. Then, the auditor can assign blame to at least $f + 1$ misbehaving or slow replicas.

Proof. First, the auditor can obtain a ledger package $\langle \mathcal{F}, \mathcal{U}, cp, \mathcal{E}, \mathcal{N} \rangle$ that is complete in relation to $\mathcal{R}$; otherwise, IA-CCF can assign blame to at least $f + 1$ misbehaving or slow replicas by Lemma 8.

Just as in Lemma 6, since the receipts in $\mathcal{R}$ violate serializability, no serial execution of $t_0, ..., t_k$ can produce $io_0, ..., io_k$. $\mathcal{F}$ is well-formed, so there are two options for its validity:

Valid ledger. Similar to Lemma 6. By Lemma 10, the auditor can assign blame to at least $f + 1$ misbehaving replicas.

Invalid ledger. Assume that receipts are ordered lexicographically based on the corresponding (sequence number, configuration number, index number, view number) tuples. (We can assume that there is no tie; otherwise the auditor can assign blame to the replicas that signed both tied receipts.)

Let R_e be the earliest receipt in the ordered $\mathcal{R}$. Let d_{C_0} be the digest in R_e. Let s_{C_0} be the sequence number with the expected checkpoint digest d_{C_0}. s_{C_0} can be calculated by the auditor using s_e, the checkpoint interval C, and the supporting governance chain. (Note that s_{C_0} is equal to $s_{\min}$ that is calculated while obtaining the ledger.)

We can assume that the batch at s_e is prepared by the same configuration that sent the receipt; otherwise the auditor can assign blame to $f + 1$ misbehaving replicas by Lemma 9. We also know that the supporting governance chain of R_e matches $\mathcal{F} + \mathcal{U}$ and that $\mathcal{F} + \mathcal{U}$ is well-formed. So, the checkpoint transactions at s_{C_0} (and $s_{C_0} + C$ if it exists) are prepared by the same configuration as R_e by definition of s_{C_0}. So, if the digest at s_{C_0} is not d_{C_0}, the auditor can assign blame to $f + 1$ misbehaving replicas similar to Lemma 6.

Since the supporting governance chains of all receipts match the ledger fragment by definition of completeness, the auditor can determine the correct stored procedures for each transaction to replay the ledger as in Lemma 6. $\square$

Theorem 3 (Linearizability violations with reconfiguration).
Let $\mathcal{R}$ be a set of receipts that violate linearizability. Then, the auditor can assign blame to at least $f + 1$ misbehaving or slow replicas.

Proof. If the receipts also violate serializability, the auditor can assign blame to at least $f + 1$ misbehaving or slow replicas by Lemma 11; otherwise, the minimum ledger index argument in the proof of Theorem 2 holds. $\square$

DispersedLedger: High-Throughput Byzantine Consensus on Variable Bandwidth Networks

Lei Yang[1], Seo Jin Park[1], Mohammad Alizadeh[1], Sreeram Kannan[2], David Tse[3]

[1]*MIT CSAIL* [2]*University of Washington* [3]*Stanford University*

Abstract

The success of blockchains has sparked interest in large-scale deployments of Byzantine fault tolerant (BFT) consensus protocols over wide area networks. A central feature of such networks is variable communication bandwidth across nodes and across time. We present DispersedLedger, an asynchronous BFT protocol that provides near-optimal throughput in the presence of such variable network bandwidth. The core idea of DispersedLedger is to enable nodes to propose, order, and agree on blocks of transactions without having to download their full content. By enabling nodes to agree on an ordered log of blocks, with a guarantee that each block is available within the network and unmalleable, DispersedLedger decouples bandwidth-intensive block downloads at different nodes, allowing each to make progress at its own pace. We build a full system prototype and evaluate it on real-world and emulated networks. Our results on a geo-distributed wide-area deployment across the Internet shows that DispersedLedger achieves 2× better throughput and 74% reduction in latency compared to HoneyBadger, the state-of-the-art asynchronous protocol.

1 Introduction

State machine replication (SMR) is a foundational task for building fault-tolerant distributed systems [25]. SMR enables a set of nodes to agree on and execute a replicated log of commands (or *transactions*). With the success of cryptocurrencies and blockchains, *Byzantine fault-tolerant SMR (BFT)* protocols, which tolerate arbitrary behavior from adversarial nodes, have attracted considerable interest in recent years [2, 5, 7, 15, 31, 39]. The deployment environment for these protocols differs greatly from standard SMR use cases. BFT implementations in blockchain applications must operate over wide-area networks (WAN), among possibly hundreds to thousands of nodes [2, 18, 31].

Large-scale WAN environments present new challenges for BFT protocols compared to traditional SMR deployments across a few nodes in datacenter. In particular, WANs are subject to *variability* in network bandwidth, both across different nodes and across time. While BFT protocols are secure in the presence of network variability, their performance can suffer greatly.

To understand the problem, let us consider the high-level structure of existing BFT protocols. BFT protocols operate in epochs, consisting of two distinct phases: (i) a *broadcast* phase, in which one or all of the nodes (depending on whether the protocol is leader-based [1, 39] or leaderless [17, 31]) broadcast a *block* (batch of transactions) to the others; (ii) an *agreement* phase, in which the nodes vote for blocks to append to the log, reaching a verifiable agreement (e.g., in the form of a quorum certificate [11]). From a communication standpoint, the broadcast phase is bandwidth-intensive while the agreement phase typically comprises of multiple rounds of short messages that do not require much bandwidth but are latency-sensitive.

Bandwidth variability hurts the performance of BFT protocols due to *stragglers*. In each epoch, the protocol cannot proceed until a super-majority of nodes have downloaded the blocks and voted in the agreement phase. Specifically, a BFT protocol on $N = 3f + 1$ nodes (tolerant to f faults) requires votes from at least $2f + 1$ nodes to make progress [11]. Therefore, the throughput of the protocol is gated by the $(f+1)^{th}$ slowest node in each epoch. The implication is that low-bandwidth nodes (which take a long time to download blocks) hold up the high-bandwidth nodes, preventing them from utilizing their bandwidth efficiently. Stragglers plague even asynchronous BFT protocols [31], which aim to track actual network performance (without making timing assumptions), but still require a super-majority to download and vote for blocks in each epoch. We show that this lowers the throughput of these protocols well below the average capacity of the network on real WANs.

In this paper, we present DispersedLedger, a new approach to build BFT protocols that significantly improves performance in the presence of bandwidth variability. The key idea behind this approach is to decompose consensus into two steps, one of which is not bandwidth intensive and the other is. First, nodes agree on an ordered log of *commitments*, where each commitment is a small digest of a block (e.g., a Merkle root [30]). This step requires significantly less bandwidth than downloading full blocks. Later, each node downloads the blocks in the agreed-upon order and executes the transactions to update its state machine. The principal advantage of this approach is that each node can download blocks at its own pace. Importantly, slow nodes do not impede
Figure 1: Impact of bandwidth variability on overall performance. Bcast: broadcast, Agmt: agreement. Fast nodes currently have a high bandwidth, while slow nodes currently have low bandwidth. (a) In traditional BFT protocols, the speed of consensus is always limited by the slow nodes since they take a long time to download the blocks. (b) DispersedLedger allows each node to download blocks at its own pace as permitted by its bandwidth.

the progress of fast nodes as long as they have a minimal amount of bandwidth needed to participate in the first step.

The key to realizing this idea is to guarantee the *data availability* of blocks. When a node accepts a commitment into the log, it must know that the block referred to by this commitment *is* available in the network and can be downloaded at a later time by any node in the network. Otherwise, an attacker can put a commitment of an unavailable block into the log, thus halting the system. To solve this problem, our proposal relies on *Verifiable Information Dispersal (VID)* [10]. VID uses erasure codes to store data across N nodes, such that it can be retrieved later despite Byzantine behavior. Prior BFT protocols like HoneyBadger [31] have used VID as a communication-efficient broadcast mechanism [10], but we use it to guarantee data availability. Specifically, unlike HoneyBadger, nodes in DispersedLedger do not wait to download blocks to vote for them. They vote as soon as they observe that a block has been *dispersed*, and the next epoch can begin immediately once there is agreement that dispersal has completed. This enables slow nodes to participate in the latest epoch, even if they fall behind on block downloads (retrieval). Such nodes can catch up on retrievals when their bandwidth improves. Figure 1 shows the structure of DispersedLedger, contrasting it to traditional BFT protocols.

Enabling nodes to participate in a consensus protocol with minimal bandwidth has applications beyond improving performance on temporally fluctuating bandwidth links. It also creates the possibility of a network with two types of

nodes: high-bandwidth nodes and low-bandwidth nodes. All nodes participate in agreeing on the ordered log of commitments, but only the high-bandwidth nodes retrieve all blocks. Network participants can choose what mode to use at any time. For example, a node running on a mobile device can operate in the low-bandwidth mode when connected to a cellular network, and switch to high-bandwidth mode on WiFi to catch up on block retrievals. All nodes, both high-bandwidth and low-bandwidth, contribute to the network's security. Our approach is also a natural way to shard a blockchain [27], where different nodes only retrieve blocks in their own shard.

We make the following contributions:

- We propose a new asynchronous VID protocol, AVID-M (§3). Compared to the current state-of-the-art, AVID-M achieves 1–2 orders of magnitudes better communication cost when operating on small blocks (hundreds of KBs to several MBs) and clusters of more than a few servers.
- We design DispersedLedger (§4), an asynchronous BFT protocol based on HoneyBadger [31] with two major improvements: (i) It decomposes consensus into data availability agreement and block retrieval, allowing nodes to download blocks asynchronously and fully utilize their bandwidth (§4.2). (ii) It provides a new solution to the censorship problem [31] that has existed in such BFT protocols since [4] (§4.3). Unlike HoneyBadger, where up to f correct blocks can get dropped every epoch, our solution guarantees that *every* correct block is delivered (and executed). The technique is applicable to similarly-constructed protocols, and can improve throughput and achieve censorship resilience without advanced cryptography [31].
- We address several practical concerns (§4.5): (i) how to prevent block retrieval traffic from slowing down dispersal traffic, which could reduce system throughput; (ii) how to prevent constantly-slow nodes from falling arbitrarily behind the rest of the network; (iii) how to avoid invalid "spam" transactions, now that nodes may not always have the up-to-date system state to filter them out.
- We implement DispersedLedger in 8,000 lines of Go (§5) and evaluate it in multiple settings (§6), including two global testbeds on AWS and Vultr, and controlled network emulations. DispersedLedger achieves a throughput of 36 MB/s when running at 16 cities across the world, and a latency of 800 ms that is stable across a wide range of load. Compared to HoneyBadger, DispersedLedger has 105% higher throughput and 74% lower latency.

2 Background and Related Work

2.1 The BFT Problem

DispersedLedger solves the problem of Byzantine-fault-tolerant state machine replication (BFT) [25]. In general, BFT assumes a server-client model, where N servers maintain N replicas of a state machine. At most f servers are Byzantine and may behave arbitrarily. Clients may submit transactions to a correct server to update or read the state machine. A

BFT protocol must ensure that the state machine is replicated across all correct servers despite the existence of Byzantine servers. Usually, this is achieved by delivering a consistent, total-ordered log of transactions to all servers (nodes) [31]. Formally, a BFT protocol provides the following properties:

- **Agreement**: If a correct server executes a transaction m, then all correct servers eventually execute m.
- **Total Order**: If correct servers p and q both execute transactions m_1 and m_2, then p executes m_1 before m_2 if and only if q executes m_1 before m_2.
- **Validity**: If a correct client submits a transaction m to a correct server, then all correct servers eventually execute m.[1]

There are multiple trust models between BFT servers and the clients. In this paper, we assume a model used for *consortium blockchains* [2,3,6,40], where servers and clients belong to organizations. Clients send their transactions through the servers hosted by their organization and trust these servers. Many emerging applications of BFT like supply chain tracing [14], medical data management [26], and cross-border transaction clearance [22] fall into this model.

2.2 Verifiable Information Dispersal

DispersedLedger relies on verifiable information dispersal (VID). VID resembles a distributed storage, where clients can *disperse* blocks (data files) across servers such that they are available for later *retrieval*. We provide a formal definition of VID in §3.1. The problem of *information dispersal* was first proposed in [37], where an erasure code was applied to efficiently store a block across N servers without duplicating it N times. [19] extended the idea to the BFT setting under the asynchrony network assumption. However, it did not consider Byzantine clients; these are malicious clients which try to cause two retrievals to return different blocks. *Verifiable* information dispersal (VID) was first proposed in [10], and solved this inconsistency problem. However, [10] requires that *every* node downloads the *full* block during dispersal, so it is no more efficient than broadcasting. The solution was later improved by AVID-FP [21], which requires each node to only download an $O(1/N)$ fraction of the dispersed data by utilizing fingerprinted cross-checksums [21]. However, because every message in AVID-FP is accompanied by the cross-checksum, the protocol provides low communication cost only when the dispersed data block is much larger than the cross-checksum (about $37N$ bytes). This makes AVID-FP unsuitable for small data blocks and clusters of more than a few nodes. In §3, we revisit this problem and propose AVID-M, a new asynchronous VID protocol that greatly reduces the per-message overhead: from $37N$ bytes to the size of a single hash (32 bytes), independent of the cluster size N, making the protocol efficient for small blocks and large clusters.

---

[1] Some recent BFT protocols provide a weaker version of validity, which guarantees execution of a transaction m only after being sent to *all* correct servers. This is referred to by different names: "censorship resilience" in HoneyBadger, and "fairness" in [8,9].

2.3 Asynchronous BFT protocols

A distributed algorithm has to make certain assumptions on the network it runs on. DispersedLedger makes the weakest assumption: *asynchrony* [28], where messages can be arbitrarily delayed but not dropped. A famous impossibility result [16] shows there cannot exist a deterministic BFT protocol under this assumption. With randomization, protocols can tolerate up to f Byzantine servers out of a total of $3f+1$ [24]. DispersedLedger achieves this bound.

Until recently [31], asynchronous BFT protocols have been costly for clusters of even moderate sizes because they have a communication cost of at least $O(N^2)$ [8]. HoneyBadger [31] is the first asynchronous BFT protocol to achieve $O(N)$ communication cost per bit of committed transaction (assuming batching of transactions). The main structure of HoneyBadger is inspired by [4], and it in turn inspires the design of other protocols including BEAT [15] and Aleph [17]. In these protocols, all N nodes broadcast their proposed blocks in each epoch, which triggers N parallel Binary Byzantine Agreement (BA) instances to agree on a subset of blocks to commit. [10] showed that VID can be used as an efficient construction of reliable broadcast, by invoking retrieval immediately after dispersal. HoneyBadger and subsequent protocols use this construction as a blackbox. BEAT [15] explores multiple trade-offs in HoneyBadger and proposes a series of protocols based on the same structure. One protocol, BEAT3, also includes a VID subcomponent. However, BEAT3 is designed to achieve BFT *storage*, which resembles a distributed key-value store.

2.4 Security Model

Before proceeding, we summarize our security model. We make the following assumptions:

- The network is asynchronous (§2.3).
- The system consists of a fixed set of N nodes (servers). A subset of at most f nodes are Byzantine, and $N \geq 3f+1$. N and f are protocol parameters, and are public knowledge.
- Messages are authenticated using public key cryptography. The public keys are public knowledge.

3 AVID-M: An Efficient VID Protocol

3.1 Problem Statement

VID provides the following two primitives: `Disperse`(B), which a client invokes to disperse block B, and `Retrieve`, which a client invokes to retrieve block B. Clients invoke the `Disperse` and `Retrieve` primitives against a particular *instance* of VID, where each VID instance is in charge of dispersing a different block. Multiple instances of VID may run concurrently and independently. To distinguish between these instances, clients and servers tag all messages of each VID instance with a unique ID for that instance. For each instance of VID, each server triggers a `Complete` event to indicate that the dispersal has completed.

A VID protocol must provide the following properties [10] for each instance of VID:

- **Termination**: If a correct client invokes `Disperse`(B) and no other client invokes `Disperse` on the same instance, then all correct servers eventually `Complete` the dispersal.
- **Agreement**: If some correct server has `Completed` the dispersal, then all correct servers eventually `Complete` the dispersal.
- **Availability**: If a correct server has `Completed` the dispersal, and a correct client invokes `Retrieve`, it eventually reconstructs some block B'.
- **Correctness**: If a correct server has `Completed` the dispersal, then correct clients always reconstruct the *same* block B' by invoking `Retrieve`. Also, if a correct client initiated the dispersal by invoking `Disperse`(B) and no other client invokes `Disperse` on the same instance, then $B = B'$.

3.2 Overview of AVID-M

At a high level, a VID protocol works by encoding the dispersed block using an erasure code and storing the encoded *chunks* across the servers. A server knows a dispersal has completed when it hears from enough peers that they have received their chunks. To retrieve a dispersed block, a client can query the servers to obtain the chunks and decode the block. Here, one key problem is verifying the correctness of encoding. Without verification, a malicious client may distribute *inconsistent* chunks that have more than one decoding result depending on which subset of chunks are used for decoding, violating the Correctness property. As mentioned in §2.2, AVID [10] and AVID-FP solve this problem by requiring servers to download the chunks or fingerprints of the chunks from all correct peers and examine them during dispersal. While this eliminates the possibility of inconsistent encoding, the extra data download required limits the scalability of these protocols.

More specifically, while AVID-FP [21] can achieve optimal communication complexity as the block size $|B|$ goes to infinity, its overhead for practical values of $|B|$ and N (number of servers) can be quite high. This is because every message in AVID-FP is accompanied by a fingerprinted cross-checksum [21], which is $N\lambda + (N-2f)\gamma$ in size. Here, λ, γ are security parameters, and we use $\lambda = 32$ bytes, $\gamma = 16$ bytes as suggested by [21]. The key factor that limits the scalability of AVID-FP is that the size of the cross-checksum is proportional to N. Combined with the fact that a node receives $O(N)$ messages during dispersal, the overhead caused by cross-checksum increases quadratically as N increases. Fig. 2 shows the impact of this overhead. At $N > 40$, $|B| = 100$ KB, every node needs to download more than the *full size* of the block being dispersed.

We develop a new VID protocol for the asynchronous network model, Asynchronous Verifiable Information Dispersal with Merkle-tree (AVID-M). AVID-M is based on one key observation: as long as clients can independently verify the encoding during *retrieval*, the servers do not need to do the verification during dispersal. In AVID-M, a client invoking `Disperse`(B) commits to the set of (possibly inconsistent)

Figure 2: *Per-node* communication cost during dispersal of AVID-M and AVID-FP normalized over the size of the dispersed block. At $N = 128$ (the biggest cluster size in our evaluation), every node in AVID-M downloads as much as $1/32$ of a block, while a node in AVID-FP downloads $1.2\times$ the size of the full block.

chunks using a short, constant-sized commitment H. Then the server-side protocol simply agrees on H and guarantees enough chunks that match H are stored by correct servers. This can be done by transmitting only H in the messages, compared to the $O(N)$-sized cross-checksums in AVID-FP. During retrieval, a client verifies that the block it decodes produces the same commitment H when re-encoded.

Since AVID-M's per-message overhead is a small constant (32 bytes), it can scale to many nodes without requiring a large block size. In fact, AVID-M achieves a per-node communication cost of $O(|B|/N + \lambda N)$, much lower than AVID-FP's $O(|B|/N + \lambda N^2 + \gamma N^2)$. Fig. 2 compares AVID-M with AVID-FP. At $|B| = 1$ MB, AVID-M is close to the theoretical lower-bound[2] even at $N > 100$, while AVID-FP stops to provide any bandwidth saving (compared to every server downloading full blocks) after $N > 120$. Finally, we note that both AVID-M and AVID-FP rely on the security of the hash. So with the same hash size λ, AVID-M is no less secure than AVID-FP.

3.3 AVID-M Protocol

The **Dispersal algorithm** is formally defined in Fig. 3. A client initiates a dispersal by encoding the block B using an $(N-2f, N)$-erasure code and constructing a Merkle tree [30] out of the encoded chunks. The root r of the Merkle tree is a secure summary of the array of the chunks. The client sends one chunk to each server along with the Merkle root r and a Merkle *proof* that proves the chunk belongs to root r. Servers then need to make sure at least $N-2f$ chunks under the same Merkle root are stored at *correct* servers for retrieval. To do that, servers exchange a round of `GotChunk`(r) messages to announce the reception of the chunk under root r. When $N - f$ servers have announced `GotChunk`(r), they know at least $N - 2f$ correct servers have got the chunk under the same root r, so they exchange a round of `Ready`(r) messages to collectively `Complete` the dispersal.

---

[2]Each node has to download at least $\frac{1}{N-2f}$-fraction of the dispersed data. This is to prevent a specific attack: a malicious client sends chunks to all f malicious servers plus $N-2f$ honest servers. For now the malicious servers do not deviate from the protocol, so the protocol must terminate (otherwise it loses liveness). Then the malicious servers do not release the chunks, so the original data must be constructed from the $N-2f$ chunks held by honest servers, so each honest server must receive an $\frac{1}{N-2f}$-fraction share.

Disperse(B) **invoker**
1. Encode the input block B using an $(N-2f,N)$-erasure code, which results in N chunks, $C_1,C_2,...,C_N$.
2. Form a Merkle tree with all chunks $C_1,C_2,...,C_N$, and calculate the Merkle tree root, r.
3. Send Chunk(r,C_i,P_i) to the i-th server. Here P_i is the Merkle proof showing C_i is the i-th chunk under root r.

Disperse(B) **handler for the i-th server**
• Upon receiving Chunk(r,C_i,P_i) from a client:
1. Check if C_i is the i-th chunk under root r by verifying the proof P_i. If not, ignore the message.
2. Set MyChunk $= C_i$, MyProof $= P_i$, MyRoot $= r$ (all initially unset).
3. Broadcast GotChunk(r) if it has not sent a GotChunk message before.
• Upon receiving GotChunk(r) from the j-th server:
1. Increment ShareCount[r] (initially 0).
2. If ShareCount[r] $\geq N-f$, broadcast Ready(r).
• Upon receiving Ready(r) from the j-th server:
1. Increment ReadyCount[r] (initittally 0).
2. If ReadyCount[r] $\geq f+1$, broadcast Ready(r).
3. If ReadyCount[r] $\geq 2f+1$, set ChunkRoot $= r$. Dispersal is Complete.

Figure 3: Algorithm for Disperse(B). Servers ignore duplicate messages (same sender and same type). When broadcasting, servers also send the message to themselves.

The **Retrieval algorithm** is formally defined in Fig 4. A client begins retrieval by requesting chunks for the block from all servers. Servers respond by providing the chunk, the Merkle root r, and the Merkle proof proving that the chunk belongs to the tree with root r. Upon collecting $N-2f$ different chunks with the same root, the client can decode and obtain a block B'. However, the client must ensure that other retrieving clients also obtain B' no matter which subset of $N-2f$ chunks they use – letting clients perform this check is a key idea of AVID-M. To do that, the client re-encodes B', constructs a Merkle tree out of the resulting chunks, and verifies that the root is the same as r. If not, the client returns an error string as the retrieved content.

The AVID-M protocol described in this section provides the four properties mentioned in §3.1. We provide a proof sketch for each property, and point to Appendix B for complete proofs.

Termination (Theorem B.2). A correct client sends correctly encoded chunks to all servers with root r. The $N-f$ correct servers will broadcast GotChunk(r) upon getting their chunk. All correct servers will receive the $N-f$ GotChunk(r) and send out Ready(r), so all correct servers will receive at least $N-f$ Ready(r). Because $N-f > 2f+1$, all correct servers will Complete.

Agreement (Theorem B.4). A server Completes after receiving $2f+1$ Ready(r), of which $f+1$ must come from correct servers. So all correct servers will receive at least

Retrieve **invoker**
• Broadcast RequestChunk to all servers.
• Upon getting ReturnChunk(r, C_i, P_i) from the i-th server:
1. Check if C_i is the i-th chunk under root r by verifying the proof P_i. If not, ignore the messsage.
2. Store the chunk C_i with the root r.
• Upon collecting $N-2f$ or more chunks with the same root r:
1. Decode using any $N-2f$ chunks with root r to get a block B'. Set ChunkRoot $= r$ (initially unset).
2. Encode the block B' using the same erasure code to get chunks $C_1',C_2',...,C_N'$.
3. Compute the Merkle root r' of $C_1',C_2',...,C_N'$.
4. Check if $r' =$ ChunkRoot. If so, return B'. Otherwise, return string "BAD_UPLOADER".

Retrieve **handler for the i-th server**
• Upon receiving RequestChunk, respond with message ReturnChunk(ChunkRoot, MyChunk, MyProof) if MyRoot $=$ ChunkRoot. Defer responding if dispersal is not Complete or any variable here is unset.

Figure 4: Algorithm for Retrieve. Clients ignore duplicate messages (same sender and same type).

$f+1$ Ready(r). This will drive all of them to send Ready(r). Eventually every correct server will receive $N-f$ Ready(r), which is enough to Complete ($N-f > 2f+1$).

Availability (Theorem B.6). To retrieve, a client must collect $N-2f$ chunks with the *same* root. This requires that at least $N-2f$ correct servers have a chunk for the same root. Now suppose that a correct server Completes when receiving $2f+1$ Ready(r). When this happens, at least one correct server has sent Ready(r). We prove that this implies that at least $N-2f$ correct servers must have sent GotChunk(r) (Lemma B.1),i.e., they have received the chunk. Assume the contrary. Then there will be less than $N-f$ GotChunk(r). Now a correct server only sends Ready(r) if it either receives (i) at least $N-f$ GotChunk(r), or (ii) at least $f+1$ Ready(r). Neither is possible (see Lemma B.1).

All correct servers agree on the same root upon Complete by setting ChunkRoot to the same value (Lemma B.5). To see why, notice that each server will only send one GotChunk per instance. If correct servers Complete with 2 (or more) ChunkRoots, then at least $N-f$ servers must have sent GotChunk for each of these roots. But $2(N-f) > N+f$, hence at least one correct server must have sent GotChunk for two different roots, which is not possible.

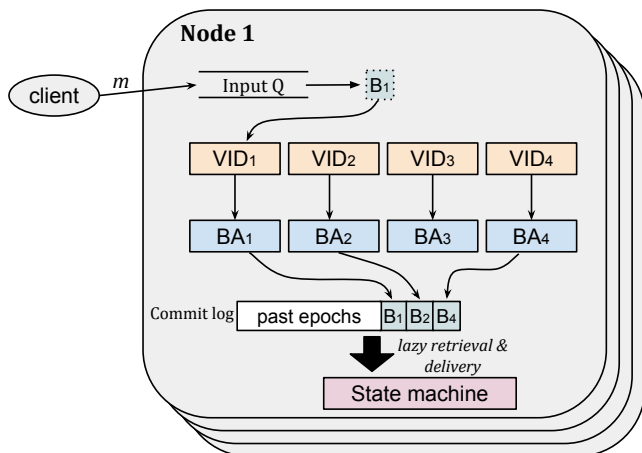
Correctness (Theorem B.9). First, note that two correct clients finishing Retrieve will set ChunkRoot to be the same, i.e., they will decode from chunks under the same Merkle root r (Lemma B.5). However, we don't know if two different subsets of chunks under r would decode to the same block, because a malicious client could disperse arbitrary data as chunks. To ensure consistency of Retrieve across


Figure 5: DispersedLedger architecture with $N = 4$. During this single epoch, 4 VIDs are initiated, one for each node, and three blocks B_1, B_2 and B_4 are committed.

different correct clients, every correct client re-encodes the decoded block B', calculates the Merkle root r' of the encoding result, and compares r' with the root r. There are two possibilities: (i) Some correct client gets $r' = r$. Then r corresponds to the chunks given by the *correct* encoding of B', so every correct client decoding from any subset of blocks under r will also get B' and $r' = r$. (ii) No correct client gets $r' = r$, i.e, all of them get $r' \neq r$. In this case, they all deliver the fixed error string. In either case, all correct clients return the same data (Lemma B.8).

4 DispersedLedger Design

4.1 Overview

DispersedLedger is a modification of HoneyBadger [31], a state-of-the-art asynchronous BFT protocol. HoneyBadger runs in epochs, where each epoch commits between $N - f$ to N blocks (at most 1 block from each node). As shown in Fig. 5, transactions submitted by clients are stored in each node's input queue. At the beginning of each epoch, every node creates a block from transactions in its input queue, and proposes it to be committed to the log in the current epoch. Once committed, all transactions in the block will eventually be retrieved and delivered to the state machine for execution.

DispersedLedger has two key differences with HoneyBadger. First, unlike HoneyBadger, a node in DispersedLedger does not broadcast its proposed block; instead, it *disperses* the proposed block among the entire cluster using AVID-M (which we will refer to as VID from here on). As shown in Fig. 5, there are N instances of VID in every epoch, one for each node. DispersedLedger then relies on N instances of Binary Agreement (BA, details below) [32] to reach a consensus on which proposed blocks have been successfully dispersed and thus should be committed in the current epoch. Once committed, a block can be retrieved by nodes lazily at any time (concurrently with future block proposals and dispersals). The asynchronous retrieval of blocks allows each node to

Figure 6: Algorithm for single-epoch DispersedLedger.

adapt to temporal network bandwidth variations by adjusting the rate it retrieves blocks without slowing down other nodes.

In HoneyBadger, up to f correct blocks can be dropped in every epoch (§4.3). This wastes bandwidth and can lead to censorship where blocks from certain nodes are always dropped [31]. DispersedLedger's second innovation is a new method, called inter-node linking, that guarantees every correct block is committed.

DispersedLedger uses an existing BA protocol [32] that completes in $O(1)$ time (parallel rounds) with $O(N\lambda)$ per-node communication cost, where λ is the security parameter. In BA, each node provides a binary $\texttt{Input}(\{0,1\})$ as input to the protocol, and may get an $\texttt{Output}(\{0,1\})$ event indicating the result of the BA instance. Formally, a BA protocol has the following properties:

- **Termination**: If all correct nodes invoke $\texttt{Input}$, then every correct node eventually gets an $\texttt{Output}$.
- **Agreement**: If any correct node gets $\texttt{Output}(b)$ ($b \in \{0,1\}$), then every correct node eventually gets $\texttt{Output}(b)$.
- **Validity**: If any correct node gets $\texttt{Output}(b)$ ($b \in \{0,1\}$), then at least one correct node has invoked $\texttt{Input}(b)$.

4.2 Single Epoch Protocol

In each epoch, the goal is to agree on a set of (the indices of) at least $N - f$ dispersed blocks which are available for later retrieval. An epoch contains N instances of VID and BA. Let VID_i^e be the i-th ($1 \leq i \leq N$) VID instance of epoch e. VID_i^e is reserved for the i-th node to disperse (propose) its block.[3] Let BA_i^e be the i-th ($1 \leq i \leq N$) BA instance of epoch e. BA_i^e is for agreeing on whether to commit the block dispersed by the i-th node.

---

[3] Correct nodes ignore attempts from another node j ($j \neq i$) to disperse into VID_i^e by dropping $\texttt{Chunk}$ messages for VID_i^e from node j ($j \neq i$). Therefore, a Byzantine node cannot impersonate and disperse blocks on behalf of others.

Fig. 6 describes the single epoch protocol for the i-th node at epoch e. It begins by taking the block B_i^e to be proposed for this epoch, and dispersing it for epoch e through VID_i^e. Note that every block in the system is dispersed using a unique VID instance identified by its epoch number and proposing node.

Nodes now need to decide which blocks get committed in this epoch, and they should only commit blocks that have been successfully dispersed. Because there are potentially f Byzantine nodes, we cannot wait for all N instances of VID to complete because Byzantine nodes may never initiate their VID `Disperse`. On the other hand, nodes cannot simply wait for and commit the first $N - f$ VIDs to `Complete`, because VID instances may `Complete` in different orders at different nodes (hence correct nodes would not be guaranteed to commit the same set of blocks). DispersedLedger uses a strategy first proposed in [4]. Nodes use BA_i^e to explicitly agree on whether to commit B_i^e (which should be dispersed in VID_i^e). Correct nodes input 1 into BA_i^e only when VID_i^e `Completes`, so BA_i^e outputs 1 only if B_i^e *is* available for later retrieval. When $N - f$ BA instances have output 1, nodes give up on waiting for any more VID to `Complete`, and input 0 into the remaining BAs to explicitly signal the end of this epoch. This is guaranteed to happen because VID instances of the $N - f$ correct nodes will always `Complete` by the Termination property (§3.1). Once the set of committed blocks are determined, nodes can start retrieving the full blocks. After all blocks have been downloaded, a node sorts them by index number and delivers (executes) them in order.

The single-epoch DispersedLedger protocol is readily chained together epoch by epoch to achieve full SMR, as pictured in Fig. 5. At the beginning of every epoch, a node takes transactions from the head of the input buffer to form a block. After every epoch, a node checks if its block is committed. If not, it puts the transactions in the block back to the input buffer and proposes them in the next epoch. Also, a node delivers epoch e only after it has delivered all previous epochs.

4.3 Inter-node Linking

Motivation. An important limitation of the aforementioned single-epoch protocol (and all protocols with a similar construction [15, 31]) is that not all proposed blocks from correct nodes are committed in an epoch. An epoch only guarantees to commit $N - f$ proposed blocks, out of which $N - 2f$ are guaranteed to come from correct nodes. In other words, at most f blocks proposed by correct nodes are dropped every epoch. Dropped blocks can happen *with or without* adversarial behavior. Transmitting such blocks wastes bandwidth, for example, reducing HoneyBadger's throughput by 25% in our experiments (§6.2). To make the matter worse, the adversary (if present) can determine which blocks to drop [31], i.e. at most f correct servers can be *censored* such that *no* block from these servers gets committed. HoneyBadger provides a partial mitigation by keeping the proposed blocks encrypted until they are committed so that the adversary cannot censor
Figure 7: An example of commits by inter-node linking where $N = 4, f = 1$. Each box indicates a block proposed by a node at an epoch. Orange blocks are committed by BA. "VID" indicates that the block is dispersed but not committed. "C-IL" indicates a block committed by inter-node linking. Blue dotted boxes indicate a VID in progress. In the current epoch, after delivering the blocks from node 1, 2, and 4, the block proposed in epoch 3 by node 2 will be delivered by inter-node linking.

blocks by their content. The adversary *can*, however, censor blocks based on the proposing node.[4] This is unacceptable for consortium blockchains (§2.4), because the adversary could censor *all* transactions from certain (up to f) organizations. Moreover, HoneyBadger's mitigation relies on threshold cryptography, which incurs a high computational cost [15].

Our solution. We propose a novel solution to this problem, called *inter-node linking*, that guarantees *all* blocks from correct nodes are committed. Inter-node linking eliminates any censorship or bandwidth waste, and is readily applicable to similarly constructed protocols like HoneyBadger and BEAT. Notice that a block not committed by BA in a given epoch may still finish its VID. For example, in Fig. 7, the block proposed by node 2 in epoch 3 was dispersed but did not get selected by BA in that epoch. The core idea is to have nodes identify such blocks and deliver them in a consistent manner in later epochs.

Each node i keeps track of which VID instances have `Completed`, in the form of an array V_i^e of size N, which stores the local view at that node. When node i starts epoch e, it populates $V_i^e[j]$ (for all $1 \leq j \leq N$) with the largest epoch number such that all node j's VID instances up to epoch $V_i^e[j]$ have completed. For example, in Fig. 7, $(4, 4, 4, 3)$ would be a valid array V for the current epoch, and would indicate that node 2's VID for epoch 3 has completed but node 4's VID in epoch 4 has not.

Each node i reports its local array V_i^e in the block B_i^e it proposes in each epoch (in addition to the normal block content). As shown in Fig. 7, the BA mechanism then commits at least $N - f$ blocks in each epoch. During retrieval for epoch e, a node first retrieves the blocks committed by BA in epoch e and delivers (executes) them as in the single-epoch protocol (§4.2). It then extracts the set of V arrays in the committed blocks, i.e. $\{V_j^e \mid j \in S_i^e\}$, and combines the information across these arrays to determine additional blocks that it should retrieve (and deliver) in this epoch. Note that $S_i^e = S_j^e$ for any two correct nodes i, j due to the Agreement property of BA, so all correct nodes

---

[4]HoneyBadger suggests sending transactions to all nodes to prevent censorship, but this isn't possible for consortium blockchains and still wastes bandwidth due to dropped blocks (§6.2).

will use the same set of observations and get the same result.[5]

Using the committed V arrays, the inter-node linking protocol computes an epoch number $E^e[j]$ for each node j. This is computed locally by each node i, but we omit the index i since all (correct) nodes compute the same value. Each node then retrieves and delivers (executes) all blocks from node j until epoch $E^e[j]$. To ensure total order, nodes sort the blocks, first by epoch number then by node index. They also keep track of blocks that have been delivered so that no block is delivered twice.

In computing $E^e[j]$, we must be careful to not get misled by Byzantine nodes who may report arbitrary data in their V arrays. For example, naively taking the largest value reported for node j across all V arrays, i.e., $\max_{k \in S_i^e} V_k^e[j]$, would allow a Byzantine node to fool others into attempting to retrieve blocks that do not exist. Instead, we take the $(f+1)^{\text{th}}$-largest value; this guarantees that at least one correct node i has reported in its array V_i^e that node j has completed all its VIDs up to epoch $E^e[j]$. Recall that by the Availability property of VID (§3.1), this ensures that these blocks are available for retrieval. Also, since all correct blocks eventually finish VID (Termination property), all of them will eventually be included in E^e and get delivered. We provide pseudocode for the full DispersedLedger protocol in Appendix C.

4.4 Correctness of DispersedLedger

We now analyze the correctness of the DispersedLedger protocol by showing it guarantees the three properties required for BFT (§2.1). Full proof is in Appendix D.

Agreement and Total Order (Theorem D.7). Transactions are embedded in blocks, so we only need to show Agreement and Total Order of *block* delivery at each correct node. Blocks may get committed and delivered through two mechanisms: BA and inter-node linking. First consider blocks committed by BA. BA's Agreement and VID's Correctness properties guarantee that (i) all correct nodes will retrieve the same set of blocks for each epoch, and (ii) they will download the same content for each block. Now consider the additional blocks committed by inter-node linking. As discussed in §4.3, correct nodes determine these blocks based on identical information (V arrays) included in the blocks delivered by BA. Hence they all retrieve and deliver the same set of blocks (Lemma D.2). Also, all correct nodes use the same sorting criteria (BA-delivered blocks sorted by node index, followed by inter-node-linked blocks sorted by epoch number and node index), so they deliver blocks in the same order.

Validity (Theorems D.5, D.6). Define "correct transactions" as ones submitted by correct clients to correct nodes (servers). We want to prove every correct transaction is eventually delivered (executed). This involves two parts: (i) correct nodes do not hang, so that every correct transaction eventually gets proposed in some correct block (Theorem D.5); (ii) all

correct blocks eventually get delivered (Theorem D.6).

For part (i), note that all BAs eventually Output, since in every epoch at least $N-f$ BAs will Output(1) (Lemma D.3), and then all correct nodes will Input(0) to the remaining BAs and drive them to termination. Further, all blocks selected by BA or inter-node linking are guaranteed to be successfully dispersed, so Retrieve for them will eventually finish. By BA's Validity property, a BA only produces Output(1) when some correct node has Input(1), which can only happen if that node sees the corresponding VID Complete. Also, as explained in §4.3, inter-node linking only selects blocks that at least one correct node observes to have finished dispersal (Lemma D.4). By the Availability property of VID (§3.1), all these blocks are available for retrieval. For part (ii), note that all correct blocks eventually finish VID (Termination property). The inter-node linking protocol will therefore eventually identify all such blocks to have completed dispersal (Lemma D.4) and deliver them (if not already delivered by BA).

4.5 Practical Considerations

Running multiple epochs in parallel. In DispersedLedger, nodes perform dispersal sequentially, proceeding to the dispersal phase for the next epoch as soon as the dispersal for the current epoch has completed (all BA instances have Output). On the other hand, the retrieval phase of each epoch runs asynchronously at all nodes. To prevent slow nodes from stalling the progress of fast nodes, it is important that they participate in dispersal at as high a rate as possible, using only remaining bandwidth for retrieval. This effectively requires prioritizing dispersal traffic over retrieval traffic when there is a network bottleneck. Furthermore, a node can retrieve blocks from multiple epochs in parallel (e.g., to increase network utilization), but it must always deliver (execute) blocks in a serial order. Ideally, we want to fully utilize the network but prioritize traffic for earlier epochs over later epochs to minimize delivery latency. Mechanisms to enforce prioritization among different types of messages are implementation-specific (§5).

Constantly-slow nodes. Since DispersedLedger decouples the progress of fast and slow nodes, a natural question is: what if some nodes are constantly slow and do not have a chance to catch up? The possibility of some nodes constantly lagging behind is a common concern for BFT protocols. A BFT protocol cannot afford to wait for the slowest servers, because they could be Byzantine servers trying to stall the system [20]. Therefore the slow servers (specifically the f slowest servers) can be left behind, unable to catch up. Essentially, there is a tension between accommodating servers that are correct but slow, and preventing Byzantine nodes from influencing the system.

DispersedLedger expands this issue beyond the f slowest servers. We discuss two simple mitigations. First, the system designer could mandate a minimum average bandwidth per node such that all correct nodes can support the target system throughput over a certain timescale T. Every node

---

[5]If a particular Retrieve returns string "BAD_UPLOADER" or the block is ill formatted, we use array $[\infty, \infty, ..., \infty]$ as the observation.

must support the required bandwidth over time T but can experience lower bandwidth temporarily without stalling other nodes. Second, correct nodes could simply stop proposing blocks when too far behind, e.g., if their retrieval is more than P epochs behind the current epoch ($P = 1$ is the same as HoneyBadger). If enough nodes fall behind and stop proposing, it automatically slows down the system. A designer can choose parameters T or P to navigate the tradeoff between bandwidth variations impacting system throughput and how far behind nodes can get.

Spam transactions. In DispersedLedger, nodes do not check the validity of blocks they propose, deferring this check to the retrieval phase. This creates the possibility of malicious servers or clients spamming the system with invalid blocks.

Server-sent spam cannot be filtered even in conventional BFT protocols, because by the time other servers download the spam blocks, they have already wasted bandwidth. Similarly, HoneyBadger must perform BA (and incur its compute and bandwidth cost) regardless of the validity of the block, because by design, all BAs must eventually finish for the protocol to make progress [31]. Therefore, server-sent spam harms DispersedLedger and HoneyBadger equally. Fortunately, server-sent spam is bounded by the fraction of Byzantine servers (f/N).

On the other hand, client-sent spam is not a major concern in consortium blockchains (§2.1). In consortium blockchains, the organization is responsible for its clients, and a non-Byzantine organization would not spam the system.[6] For these reasons, some BFT protocols targeting consortium blockchains such as HyperLedger Fabric [2] forgo transaction filtering prior to broadcast for efficiency and privacy gains.

In more open settings, where clients are free to contact any server, spamming is a concern. A simple modification to the DispersedLedger protocol enables the same level of spam filtering as HoneyBadger. Correct nodes simply stop proposing new transactions when they are lagging behind in retrieval. Instead, they propose an empty block (with no transactions) to participate in the current epoch. In this way, correct nodes only propose transactions when they can verify them. Empty blocks still incur some overhead, so a natural question is: what is the performance impact of these empty blocks? Our results show that it is minor and this variant of DispersedLedger, which we call "DL-Coupled", retains most of the performance benefits (§6.2).

5 Implementation

We implement DispersedLedger in 8,000 lines of Go. The core protocol of DispersedLedger is modelled as 4 nested IO automata: `BA`, `VID`, `DLEpoch`, and `DL`. `BA` implements the binary agreement protocol proposed in [32]. `VID` implements our verifiable information dispersal protocol AVID-M

described in §3.3. We use a pure-Go implementation of Reed-Solomon code [36] for encoding and decoding blocks, and an embedded key-value storage library [23] for storing blocks and chunks. `DLEpoch` nests N instances of `VID` and `BA` to implement one epoch of DispersedLedger (§4.2). Finally, `DL` nests multiple instances of `DLEpoch` and the inter-node linking logic (§4.3) to implement the full protocol.

Traffic prioritization. Prioritizing dispersal traffic over retrieval is made complicated because nodes cannot be certain of the bottleneck capacity for different messages and whether they share a common bottleneck. For example, rate-limiting the low-priority traffic may result in under-utilization of the network. Similarly, simply enforcing prioritization between each individual pair of nodes may lead to significant priority inversion if two pairs of nodes share the same bottleneck. In our implementation, we use a simple yet effective approach to achieve prioritization in a work conserving manner (without static rate limits) inspired by MulTcp [13]. For each pair of nodes, we establish two connections, and we modify the parameters of the congestion control algorithm of one connection so that it behaves like T ($T > 1$) connections . We then send high-priority traffic on this connection, and low-priority traffic on the other (unmodified) connection. At all bottlenecks, the less aggressive low-priority connection will back off more often and yield to the more aggressive high-priority connection. On average, a high-priority connection receives T times more bandwidth than a competing low-priority connection at the same bottleneck.[7] Note that in DispersedLedger, high-priority traffic consists of only a tiny fraction of the total traffic that a node handles ($1/20$ to $1/10$ in most cases as shown in §6.4), and its absolute bandwidth is low. Therefore our approach will not cause congestion to other applications competing at the same bottleneck. In our system, we set $T = 30$. We use QUIC as the underlying transport protocol and modify the `quic-go` [12] library to add the knob T for tuning the congestion control.

To prioritize retrieval traffic by epoch, we order retrieval traffic on a per-connection basis by using separate QUIC streams for different epochs. We modify the scheduler `quic-go` [12] to always send the stream with the lowest epoch number.

Rate control for block proposal. DispersedLedger requires some degree of batching to amortize the fixed cost of BA and VID. However, if unthrottled, nodes may propose blocks too often and the resulting blocks could be very small, causing low bandwidth efficiency. More importantly, since dispersal traffic is given high priority, the system may use up all the bandwidth proposing inefficient small blocks and leave no bandwidth for block retrieval. To solve this problem, our implementation employs a simple form of adaptive batching [29]. Specifically, we limit the block proposal rate using Nagle's algorithm [33]. A node only proposes a new block if

---

[6] A Byzantine organization could of course spam, but this is the same as the server-sent spamming scenario, in which DispersedLedger is no worse than HoneyBadger.

[7] Similar approaches have been used in other usecases to control bandwidth sharing among competing flows [34].

(i) a certain duration has passed since the last block was proposed, or (ii) a certain amount of data has accumulated to be proposed in the next block. In our implementation, we use 100 ms as the delay threshold, and 150 KB as the size threshold. This setup works well for all of our evaluation experiments.

6 Evaluation

Our evaluation answers the following questions:

1. What is the throughput and the latency of DispersedLedger in a realistic deployment?
2. Is DispersedLedger able to consistently achieve good throughput regardless of network variations?
3. How does the system scale to more nodes?

We compare DispersedLedger (DL) with the original HoneyBadger (HB) and our optimized version: HoneyBadger-Link. HoneyBadger-Link (HB-Link) combines the inter-node linking in DispersedLedger with HoneyBadger, so that every epoch, all (instead of $N-2f$) honest blocks are guaranteed to get into the ledger. We also experiment with DL-Coupled, a variant of DispersedLedger where nodes only propose new transactions when they are up-to-date with retrievals (§4.5).

6.1 Experimental Setup

We run our evaluation on AWS EC2. In our experiments, every node is hosted by an EC2 `c5d.4xlarge` instance with 16 CPU cores, 16 GB of RAM, 400 GB of NVMe SSD, and a 10 Gbps NIC. The nodes form a fully connected graph, i.e. there is a link between every pair of nodes. We run our experiments on two different scenarios. First, a *geo-distributed* scenario, where we launch VMs at 16 major cities across the globe, one at each city. We don't throttle the network. This scenario resembles the typical deployment of a consortium blockchain. In addition, we measure the throughput of the system on another testbed on Vultr (details are in Appendix A.2). Second, a *controlled* scenario, where we start VMs in one datacenter and apply artificial delay and bandwidth throttling at each node using Mahimahi [35]. Specifically, we add a one-way propagation delay of 100 ms between each pair of nodes to mimic the typical latency between distant major cities [38], and model the ingress and egress bandwidth variation of each node as independent Gauss-Markov processes (more details in §6.3). This controlled setup allows us to precisely define the variation of the network condition and enables fair, reproducible evaluations. Finally, to generate the workload for the system, we start a thread on each node that generates transactions in a Poisson arrival process.

6.2 Performance over the Internet

First, we measure the performance of DispersedLedger on our geo-distributed testbed and compare it with HoneyBadger.
Throughput. To measure the throughput, we generate a high load on each node to create an infinitely-backlogged system, and report the rate of confirmed transactions at each node. Because the internet bandwidth varies at different locations, we expect the measured throughput to vary as well. Fig. 8
Figure 8: Throughput of each server running different protocols on the geo-distributed setting.
(a) DispersedLedger   **(b)** HoneyBadger with linking

Figure 9: The amount of confirmed data over time when running DispersedLedger and HoneyBadger with inter-node linking on the geo-distributed testbed, plotted on the same scale. Each line represents one server.

shows the results. DispersedLedger achieves on average 105% better throughput than HoneyBadger. To confirm that our scheme is robust, we also run the experiment on another testbed using a low-cost cloud vendor. Results in §A.2 show that DispersedLedger significantly improves the throughput in that setting as well.

DispersedLedger gets its throughput improvement mainly for two reasons. First, inter-node linking ensures all blocks that successfully finish VID get included in the ledger, so no bandwidth is wasted. In comparison, in every epoch of HoneyBadger at most f blocks may *not* get included in the final ledger. The bandwidth used to broadcast them is therefore wasted. As a result, inter-node linking provides at most a factor of $N/(N-f)$ improvement in effective throughput. To measure the gain in the real-world setting, we modify HoneyBadger to include the same inter-node linking technique and measure its throughput. Results in Fig. 8 show that enabling inter-node linking provides a 45% improvement in throughput on our geo-distributed testbed.

Second, confirmation throughput at different nodes are decoupled, so temporary slowdown at one site will not affect the whole system. Because the system is deployed across the WAN, there are many factors that could cause the confirmation throughput of a node to fluctuate: varying capacity at the network bottleneck, latency jitters, or even behavior of the congestion control algorithm. In HoneyBadger, the confirmation progress of all but the f slowest nodes are coupled, so at any time the whole system is only as fast as the $f+1$-slowest node. DispersedLedger does not have this limitation. Fig. 9 shows an example: DispersedLedger allows each node to always run at its own capacity. HoneyBadger couples the performance of most servers together, so all servers can only progress at the same, limited rate. In fact, notice that

every node makes more progress with DispersedLedger compared to HoneyBadger (with linking) over the 2 minutes shown. The reason is that with HoneyBadger, different nodes become the straggler (the $(f+1)^{\text{th}}$-slowest node) at different time, stalling all other nodes. But with DispersedLedger, a slow node whose bandwidth improves can accelerate and make progress independently of others, making full use of time periods when it has high bandwidth. Fig. 8 shows that DispersedLedger achieves 41% better throughput compared to HoneyBadger with linking due to this improvement.

Finally, DL-Coupled is 12% slower than DL on average, but it still achieves 80% and 23% higher throughput on average than HoneyBadger and HoneyBadger with linking. Recall that DL-Coupled constrains nodes that can propose new transactions to prevent spamming attacks. The result shows that in open environments where spamming is a concern, DL-Coupled can still provide significant performance gains. In the rest of the evaluation, we focus on DL (without spam mitigation) to investigate our idea in its purest form.

Latency. Confirmation latency is defined as the elapsed time from a transaction entering the system to it being delivered. Similar to the throughput, the confirmation latency at different servers varies due to heterogeneity of the network condition. Further, for a particular node, we only calculate the latency of the transactions that this node *itself* generates, i.e. *local* transactions. This is a somewhat artificial metric, but it helps isolate the latency of each server in HoneyBadger and makes the results easier to understand. In HoneyBadger, a slow node only proposes a new epoch after it has confirmed the previous epoch, so the rate it proposes is coupled with the rate it confirms, i.e. it proposes 1 block after downloading $O(N)$ blocks. Due to this reason, an overloaded node does not have the capacity to even *propose* all the transactions it generates, and whatever transaction it proposes will be stale. When these stale transactions get confirmed at a fast node, the latency (especially the tail latency) at the fast nodes will suffer. Note that DispersedLedger does not have this problem, because all nodes, even overloaded ones, propose new transactions at a rate limited only by the egress bandwidth. In summary, choosing this metric is only advantageous to HoneyBadger, so the experiment remains fair. In Appendix §A.1, we provide further details and report the latency of all servers calculated for both local only, and all transactions.

We run the system at different loads and report the latency at each node. In Fig. 10, we focus on two datacenters: Mumbai, which has limited internet connection, and Ohio, which has good internet connection. We first look at the median latency. At low load, both HoneyBadger and DispersedLedger have similarly low median latency. But as we increase the load from 6 MB/s to 15 MB/s, the median latency of HoneyBadger increases almost linearly from around 800 ms to 3000 ms. This is because in HoneyBadger, proposing and confirming an epoch are done in lockstep. As the load increases, the proposed block becomes larger and
Figure 10: The median latency of DispersedLedger (solid) and HoneyBadger (dash) under different offered load. Error bar shows the 5-th and the 95-th percentiles. Two locations with good (Ohio) and limited (Mumbai) internet connection are highlighted.

takes longer to confirm. This in turn causes more transactions to be queued for the next block so the next proposed block remains large. Actually, the batch (all blocks in an epoch) size of HoneyBadger increases from 3.4 MB to 42.5 MB (200 KB to 2.5 MB per block) as we increase the load from 6 MB/s to 15 MB/s. Note that the block size is not chosen by us, but is naturally found by the system itself. In comparison, the latency of DispersedLedger only increases by a bit when the load increases, from 730 ms to 830 ms as we increase the load from 2 MB/s to 23 MB/s. The batch size ranges between 0.85 MB to 11.9 MB (50 KB to 700 KB per block).

We now look at the tail latency, which is important for service quality. At low load (6 MB/s), the 99-th percentile latency of DispersedLedger is 1000 ms across all servers, while that of HoneyBadger ranges from 1500 ms to 4500 ms. It suggests that DispersedLedger is more stable. As we increase the load, the tail (95-th percentile) latency of the Mumbai server immediately goes up. This is because HoneyBadger does not guarantee all honest blocks to be included in the ledger, and slow nodes are more likely to see their blocks being dropped from an epoch. When it happens, the node has to re-propose the same block in the next epoch, causing significant delay to the block. We note that the tail latency of the Ohio server goes up as well. In comparison, the tail latency of DispersedLedger at both Mumbai and Ohio stays low until very high load.

6.3 Controlled experiments

In this experiment, we run a series of tests in the controlled setting to verify if DispersedLedger achieves its design goal: achieving good throughput regardless of network variation. We start 16 servers in one datacenter, and add an artificial one-way propagation delay of 100 ms between each pair of servers to emulate the WAN latency. We then generate synthetic traces for each server that independently caps the ingress and egress bandwidth of the server. For each set of traces, we measure the throughput of DispersedLedger and HoneyBadger.

Spatial variation. This is the situation where the bandwidth varies across different nodes but stays the same over time. For the *i*-th node ($0 \leq i < 16$), we set its bandwidth to constantly be $10 + 0.5i$ MB/s. Fig. 11a shows that the throughput of
(a) Spatial variation   **(b)** Temporal variation

Figure 11: Throughput of HoneyBadger (HB), HoneyBadger with linking (HB-Link), and DispersedLedger (DL) in the controlled experiments. Error bars in (b) show the standard deviation.

Figure 12: Throughput at different cluster size and block size. Error bars show the standard deviation.

Figure 13: Fraction of dispersal traffic versus total traffic at different scale and block size.

HoneyBadger (with or without linking) is capped at the bandwidth of the fifth slowest server, and the bandwidth available at all faster servers are not utilized. In comparison, the throughput of DispersedLedger at different servers are fully decoupled. The achieved bandwidth is proportional to the available bandwidth at each server. DispersedLedger achieves this because it decouples block retrieval at different servers.

Temporal variation. We now look at the scenario where the bandwidth varies over time, and show that DispersedLedger is robust to network fluctuation. We model the bandwidth variation of each node as independent Gauss-Markov processes with mean b, variance σ, and correlation between consecutive samples α, and generate synthetic traces for each node by sampling from the process every 1 second. Specifically, we set $b = 10$ MB/s, $\sigma = 5$ MB/s, $\alpha = 0.98$ and generate a trace for each server, i.e. the bandwidth of each server varies independently but have the same distribution with mean bandwidth 10 MB/s. (We show an example of such trace in §A.3.) As a comparison, we also run an experiment when the bandwidth at each server does not fluctuate and stays at 10 MB/s. In our implementation (for all protocols), a node notifies others when it has decoded a block to stop sending more chunks. This optimization is less effective when all nodes have exactly the same fixed bandwidth because all chunks for a block will arrive at roughly the same time. So in this particular experiment, we disable this optimization to enable an apple-to-apple comparison of the fixed and variable bandwidth scenarios. Fig. 11b shows that as we introduce temporal variation of the network bandwidth, the throughput of DispersedLedger stays the same. This confirms that DispersedLedger is robust to network fluctuation. Meanwhile, the throughput of HoneyBadger and HoneyBadger with linking dropped by 20% and 25% respectively.

6.4 Scalability

In this experiment, we evaluate how DispersedLedger scales to a large number of servers. As with many evaluations of BFT protocols [31, 39], we use cluster sizes ranging from 16 to 128.

Throughput. We first measure the system throughput at different cluster size N. For this experiment, we start all the servers in the same datacenter with a 100 ms one-way propagation delay on each link and a 10 MB/s bandwidth cap on each server. We also fix the block size to 500 KB
and 1 MB. Fig. 12 shows that the system throughput slightly drops when N grows 8 times bigger from 16 nodes to 128 nodes. This is because the BA in the dispersal phase has a per-node cost of $O(N^2)$. With a constant block size, the messaging overhead takes a larger fraction as N increases. We notice that increasing the block size helps amortize the cost of VID and BA, and results in better system throughput. **Traffic for block dispersal.** A metric core to the design of DispersedLedger is the amount of data a node has to download in order to participate in block dispersal, i.e. dispersal traffic. More precisely, we are interested in the *ratio* of dispersal traffic to the total traffic (dispersal plus retrieval). The lower this ratio, the easier it is for slow nodes to keep up with block dispersal, and the better DispersedLedger achieves its design goal. Fig. 13 shows this ratio at different scales and block sizes. First, we observe that increasing the block size brings down the fraction of dispersal traffic. This is because a large block size amortizes the fixed cost in VID and BA. Meanwhile, increasing the cluster size reduces the lower bound on the fraction of dispersal traffic. This is because in the VID phase, every node is responsible for an $1/(N-2f)$ slice of each block, and increasing N brings down this fraction.

7 Conclusion

We presented DispersedLedger, a new asynchronous BFT protocol that provides near-optimal throughput under fluctuating network bandwidth. DispersedLedger is based on a novel restructuring of BFT protocols that decouples agreement from the bandwidth-intensive task of downloading blocks. We implement a full system prototype and evaluate DispersedLedger on two testbeds across the real internet and a controlled setting with emulated network conditions. Our results on a wide-area deployment across 16 major cities show that DispersedLedger achieves $2\times$ better throughput and 74% lower latency compared to HoneyBadger. Our approach could be applicable to other BFT protocols, and enables new applications where resilience to poor network condition is vital.

A Supplements to the Evaluations

A.1 Latency metric

Here we justify counting only local transactions when calculating the confirmation latency. As mentioned in §6.2, we choose this metric to prevent overloaded servers from impacting the latency (especially the tail latency) of non-overloaded servers. Fig. 14 shows the latency of DispersedLedger and HoneyBadger under two metrics: counting all transactions, and counting only local transactions. Each system is running near its capacity. We observe that the latency (both the median and the tail) of DispersedLedger is the same under the two metrics, so choosing to count only local transactions in no way helps our protocol. For HoneyBadger, we observe that by counting all transactions, the median latency of the overloaded servers decreased. This is because the overloaded servers cannot get their local transactions into the ledger (so the local transactions have high latency), but can confirm *some* transactions from other non-overloaded servers. The median latency mostly represents these non-local transactions. Still, these servers are overloaded, and the latency numbers are meaningless because they will increase as system runs for longer. So the latency metric does not matter for the overloaded servers. Meanwhile, we observe that the tail latency of HoneyBadger on non-overloaded servers worsens a lot as we switch to counting all transactions. This is due to the transactions proposed by the overloaded nodes, and is the main reason that we choose to count only local transactions. In summary, counting only local transactions for latency calculation does not improve the latency of DispersedLedger, but helps improve the tail latency of non-overloaded servers in HoneyBadger, so choosing this metric is fair.

A.2 Throughput on another testbed over the internet

To further confirm that DispersedLedger improves the throughput of BFT protocols when running over the internet, we build another testbed on a low-cost cloud provider called Vultr. We use the $80/mo plan with 6 CPU cores, 16 GB of RAM, 320 GB of SSD, and an 1 Gbps NIC. At the moment of the experiment, Vultr has 15 locations across the globe, and
(a) DispersedLedger
(b) HoneyBadger

Figure 14: Confirmation latency of DispersedLedger and HoneyBadger when counting all transactions (All Tx) or only local transactions. Each system runs near its capacity (14.8 MB/s for HoneyBadger and 23.4 MB/s for DispersedLedger). The error bar shows the 5-th and 95-th percentiles.
Figure 15: Throughput of each server running different protocols on the Vultr testbed. HB stands for HoneyBadger, HB-Link stands for HoneyBadger with inter-node linking, New stands for DispersedLedger.

we run one server at each location and perform the same experiment as in § 6.2. Fig. 15 shows the results. DispersedLedger improves the throughput by at least 50% over HoneyBadger.

A.3 Example trace of temporal variation

We provide in Fig. 16 an example of the synthetic bandwidth trace we used in the temporal variation scenario in §6.3.
Figure 16: A bandwidth trace we used in the temporal variation scenario.

B Correctness proof of AVID-M

Notations. We use the symbol "·" as placeholders in message parameters to indicate "any". For example, $\text{Chunk}(r, \cdot, \cdot)$ means "Chunk messages with the first parameter set to r and the other two parameters set to any value".

Lemma B.1. *If a correct server sends* $\text{Ready}(r)$*, then at least one correct server has received* $N-f$ $\text{GotChunk}(r)$*.*

Proof. A correct server broadcasts $\text{Ready}(r)$ in two cases:
1. Having received $N-f$ $\text{GotChunk}(r)$ messages.
2. Having received $f+1$ $\text{Ready}(r)$ messages.

If a correct server sends out $\text{Ready}(r)$ for the aforementioned reason 1, then this already satisfies the lemma we want to prove. Now assume that a correct server sends $\text{Ready}(r)$ because it has received $f+1$ $\text{Ready}(r)$ (the aforementioned reason 2). Then there must exist a correct server which has sent out $\text{Ready}(r)$ because of the aforementioned reason 1. Otherwise, there can be at most f $\text{Ready}(r)$ messages (forged by the f Byzantine servers), and no correct server will ever send $\text{Ready}(r)$ because of reason 2, which contradicts with our assumption. So there exists a correct server that has received $N-f$ $\text{GotChunk}(r)$, and this satisfies the lemma. $\quad\square$

Theorem B.2 (Termination). *If a correct client invokes* Disperse *and no other client invokes* Disperse *on the same instance of VID, then all correct servers eventually* Complete *the dispersal.*

Proof. A correct client sends correctly encoded chunks to all servers. Let's assume the Merkle root of the chunks is r, then all correct servers eventually receive $\text{Chunk}(r, \cdot, \cdot)$. Because there is no other client invoking Disperse, it is impossible for a server to receive $\text{Chunk}(r', \cdot, \cdot)$ for any $r' \neq r$, and no correct server will ever broadcast $\text{GotChunk}(r')$ for any $r' \neq r$. So each correct server will send out $\text{GotChunk}(r)$. Eventually, all correct servers will receive $N-f$ $\text{GotChunk}(r)$.

All correct servers will broadcast $\text{Ready}(r)$ upon receiving these $N - f$ $\text{GotChunk}(r)$ messages or they have already sent $\text{Ready}(r)$. A correct server will Complete upon receiving $2f + 1$ $\text{Ready}(r)$. We have shown that all $N-f$

correct servers will eventually send Ready(r). Because $N - f \geq 2f + 1$, all correct servers will Complete. $\square$

Lemma B.3. *If a correct server has sent out* Ready(r)*, then no correct server will ever send out* Ready(r') *for any* $r' \neq r$.

Proof. Let's assume for contradiction that two messages Ready(r) and Ready(r') ($r \neq r'$) have both been sent by correct servers. By Lemma B.1, at least one correct server has received $N - f$ GotChunk(r), and at least one correct server has received $N - f$ GotChunk(r') ($r' \neq r$).

We obtain a contradiction by showing that the system cannot generate $N - f$ GotChunk(r) messages plus $N - f$ GotChunk(r') messages for the two correct servers to receive. Assume h GotChunk(r) messages come from correct servers, h' GotChunk(r') come from correct servers, and there are β Byzantine servers ($\beta \leq f$ by the definition of f). Then we have

$$h + \beta \geq N - f$$
$$h' + \beta \geq N - f.$$

A correct server do not broadcast *both* GotChunk(r) and GotChunk(r'), while a Byzantine server is free to send different GotChunk messages to different correct servers, so we have

$$h + h' + \beta \leq N.$$

These constraints imply

$$\beta \geq N - 2f.$$

However, $\beta \leq f$, so we must have $N \leq 3f$. This contradicts with our assumption of $N \geq 3f + 1$ in our security model (§2.4), so it is impossible, and the assumption must not hold. $\square$

Theorem B.4 (Agreement). *If some correct server* Complete*s the dispersal, then all correct servers will eventually* Complete *the dispersal.*

Proof. A correct server Completes if and only if it has received $2f + 1$ Ready(r) messages. We want to prove that in this situation, all correct servers will eventually *send* a Ready(r), so that they will all *receive* at least $2f + 1$ Ready(r) messages needed to Complete.

We now assume a correct server has Completed after receiving $2f + 1$ Ready(r). Out of these messages, at least $f + 1$ must be broadcast from correct servers, so all correct servers will eventually receive these Ready(r). A correct server will send out Ready(r) upon receiving $f + 1$ Ready(r), so all correct servers will do so upon receiving the aforementioend $f + 1$ Ready(r) messages.

Because all correct servers will send Ready(r), eventually all correct servers will receive $N - f$ Ready(r). Because $N - f \geq 2f + 1$, all of them will Complete. $\square$

Lemma B.5. *If a correct server has* Complete*d, then all correct servers eventually set the variable* ChunkRoot *to the same value.*

Proof. A correct server uses ChunkRoot to store the root of the chunks of the dispersed block, so we are essentially proving that all correct servers agree on this root. Assume that a server Completes, then it must have received $2f + 1$ Ready(r) messages. We now prove that no correct server can ever receive $2f + 1$ Ready(r') messages for any $r' \neq r$. Because a correct server has received $2f + 1$ Ready(r), there must be $f + 1$ correct servers who have broadcast Ready(r). By Lemma B.3, no correct server will ever broadcast Ready(r') for any $r' \neq r$, so a correct server can receive at most f Ready(r') for any $r' \neq r$, which are forged by the f Byzantine servers.

By Theorem B.4, all correct servers eventually Complete, so they must eventually receive $2f + 1$ Ready(r), and will each set ChunkRoot $= r$. $\square$

Theorem B.6 (Availability). *If a correct server has* Complete*d, and a correct client invokes* Retrieve*, it eventually reconstructs some block* B'.

Proof. The Retrieve routine returns at a correct client as long as it can collect $N - 2f$ ReturnChunk(r, C_i, P_i) messages with the same root r and valid proofs P_i. A correct server sends ReturnChunk(MyRoot,MyChunk,MyProof) to a client as long as it has MyRoot, MyChunk, MyProof, and ChunkRoot set, and MyRoot $=$ ChunkRoot. Here, a server uses MyRoot to store the root of the chunk it has received, uses MyChunk to store the chunk, and uses MyProof to store the Merkle proof (Fig. 3). We now prove that if any correct server Completes, at least $N - 2f$ correct servers will eventually meet this condition and send ReturnChunk to the client.

Assume that a correct server has Completed the VID instance with ChunkRoot set to r. Then, by Lemmas B.4, B.5, all correct servers will eventually Complete and set ChunkRoot $= r$. Also, this server must have received $2f + 1$ Ready(r) messages, out of which at least $f + 1$ must come from correct servers. According to Lemma B.1, at least one correct server has received $N - f$ GotChunk(r). At least $N - 2f$ GotChunk(r) messages must come from correct servers, so they each must have MyChunk, MyProof set, and have set MyRoot $= r$.

We have proved that at least $N - 2f$ correct servers will send ReturnChunk(r, C_i, P_i) messages. For each message sent by the i-th server (which is correct), P_i must be a valid proof showing C_i is the i-th chunk under root r, because the server has validated this proof. So the client will eventually obtain the $N - 2f$ chunks needed to reconstruct a block. $\square$

Lemma B.7. *Any two correct clients finishing* Retrieve *have their variable* ChunkRoot *set to the same value.*

Proof. A client uses variable ChunkRoot to store the root of the $N - 2f$ chunks it uses to reconstruct the block (Fig. 4),

so we are essentially proving that any two correct clients will use chunks under the same root when executing `Retrieve`. Let's assume for contradiction that two correct clients finish `Retrieve`, but have set `ChunkRoot` to r and r' respectively ($r \neq r'$). This implies that one client has received at least $N - 2f$ `ReturnChunk`$(r, \cdot, \cdot)$ messages, and the other has received $N - 2f$ `ReturnChunk`$(r', \cdot, \cdot)$ messages. Out of these messages, at least $N-3f$ `ReturnChunk`$(r,\cdot,\cdot)$ and at least $N-3f$ `ReturnChunk`$(r',\cdot,\cdot)$ are from correct servers (because $N \geq 3f + 1$ by our security assumptions in §2.4). Since a correct server ensures `MyRoot = ChunkRoot` and uses `MyRoot` as the first parameter of `ReturnChunk` messages, there must exist some correct server with `ChunkRoot` set to r, and some correct server with `ChunkRoot` set to r'. Also, since a correct server only sends `ReturnChunk` when it has `Completed`, there must be some server which has `Completed`. This contradicts with Lemma B.5, which states that all correct servers must have `ChunkRoot` set to the same value. The assumption must not hold. □

Extra notations. To introduce the following lemma, we need to define a few extra notations. Let `Encode`(B) be the encoding result of a block B in the form of an array of N chunks. Let `Decode`(C) be the decoding result (a block) of an array of $N-2f$ chunks. Let `MerkleRoot`(C) be the Merkle root of an array of chunks.

Lemma B.8. *For any array of N chunks C, exactly one of the following is true:*
1. *For any two subsets D_1, D_2 of $N - 2f$ chunks in C, `Decode`$(D_1) = $`Decode`$(D_2)$.*
2. *For any subset D of $N - 2f$ chunks in C, `MerkleRoot`$($`Encode`$($`Decode`$(D))) \neq $`MerkleRoot`$(C)$.*

Proof. We are proving that a set of chunks C is either:
1. Correctly encoded (consistent), so any subset of $N-2f$ chunks in C decode into the same block.
2. Or, no matter which subset of $N-2f$ chunks in C are used for decoding, a correct client can re-encode the decoded block, compute the Merkle root over the encoding result, and find it to be *different* from the Merkle root of C, and thus detect an encoding error.

Case 1: Consistent encoding. Assume for any subset D of $N-2f$ chunks in C, `Decode`$(D) = B$. We now want to prove that `MerkleRoot`$($`Encode`$($`Decode`$(D))) = $`MerkleRoot`$(C)$. By our assumption, `Encode`$($`Decode`$(D)) = $`Encode`$(B)$, so we only need to show $C = $`Encode`$(B)$. This is clearly true by the definition of erasure code: the `Encode` function encodes B into a set of N chunks, of which any subset of $N - 2f$ chunks will decode into B. C already satisfies this property, and the `Encode` process is deterministic, so it must be `Encode`$(B) = C$, and the lemma is satisfied in this case.

Case 2: Inconsistent encoding. Assume there exist two subsets D_1, D_2 of $N - 2f$ chunks in C, and `Decode`$(D_1) \neq $`Decode`$(D_2)$. Let `Decode`$(D_1) = B_1$

and `Decode`$(D_2) = B_2$ where $B_1 \neq B_2$. We want to prove that for any subset D of $N - 2f$ chunks in C, `MerkleRoot`$($`Encode`$($`Decode`$(D))) \neq $`MerkleRoot`$(C)$.

We prove it by showing there does *not* exist any block B such that $C = $`Encode`$(B)$. That is, C is not a consistent encoding result of any block. Assume for contradiction that there exists B' such that $C = $`Encode`$(B')$. Because D_1 is a subset of $N-2f$ chunks in C and `Decode`$(D_1) = B_1$, it must be $B_1 = B'$, otherwise the semantic of erasure code is broken. For the same reason $B_2 = B'$, so $B_1 = B_2$. However it contradicts with $B_1 \neq B_2$, so the assumption must not hold, and there does not exist any block B such that $C = $`Encode`$(B)$.

We now prove that `MerkleRoot`$($`Encode`$($`Decode`$(D))) \neq $`MerkleRoot`$(C)$ for any subset D of $N - 2f$ chunks in C. Assume for contradiction that `MerkleRoot`$($`Encode`$($`Decode`$(D))) = $`MerkleRoot`$(C)$, then it must be that $C = $`Encode`$($`Decode`$(D))$ because Merkle root is a secure summary of the chunks. This contradicts with the result we have just proved: there does not exist any block B such that $C = $`Encode`$(B)$. So the assumption cannot hold, and the lemma is satisfied in this case. □

Theorem B.9 (Correctness)**.** *If a correct server has `Completed`, then correct clients always reconstruct the same block B' by invoking `Retrieve`. Also, if a correct client initiated the dispersal by invoking `Disperse`(B) and no other client invokes `Disperse`, then $B = B'$.*

Proof. We first prove the first half of the theorem: any two correct clients always return the same data upon finishing `Retrieve`. By Lemma B.7, any two clients will set their `ChunkRoot` to the same value. Note that a client sets `ChunkRoot` to the root of the chunks it uses for decoding. This implies that any two correct clients will use subsets from the *same* set of chunks. By Lemma B.8, either:
1. They both decode and obtain the same block B'.
2. Or, they each compute `MerkleRoot`$($`Encode`$())$ on the decoded block and both get a result that is different from `ChunkRoot`.

In the first situation, both clients will return B'. In the second situation, they both return the block containing string "BAD_UPLOADER". In either case, they return the same block.

We then prove the second half of the theorem. Assume a correct client has initiated `Disperse`(B) and no other client invokes `Disperse`. By Theorem B.6, any correct client invoking `Retrieve` will obtain some block B'. We now prove that $B' = B$. Assume for contradiction that $B' \neq B$. Then the client must have received $N - 2f$ `ReturnChunk`$($`MerkleRoot`$($`Encode`$(B')), \cdot, \cdot)$ messages. At least one of them must come from a correct server because $N - 2f > f$, so at least one correct server have `ChunkRoot` set to `MerkleRoot`$($`Encode`$(B'))$. However, because there is only invocation of `Disperse`(B), all correct servers must have set `ChunkRoot` to `MerkleRoot`$($`Encode`$(B))$.

Phase 1. Dispersal at the i-th server

1. For $1 \le j \le N$, let $V_i^e[j]$ be the largest epoch number t such that $\text{VID}_j^1, \text{VID}_j^2, ..., \text{VID}_j^t$ have Completed.
2. Let B_i^e be the block to disperse (propose) for epoch e. B_i^e contains two parts: transactions T_i^e and observation V_i^e.
3. Invoke $\text{Disperse}(B_i^e)$ on VID_i^e as a client.
- Upon Complete of VID_j^e ($1 \le j \le N$), if we have not invoked Input on BA_j^e, invoke $\text{Input}(1)$ on BA_j^e.
- Upon $\text{Output}(1)$ of least $N-f$ BA instances, invoke $\text{Input}(0)$ on all remaining BA instances on which we have not invoked Input.
- Upon Output of all BA instances,
  1. Let local variable $S_i^e \subset \{1...N\}$ be the indices of all BA instances that $\text{Output}(1)$. That is, $j \in S$ if and only if BA_j^e has $\text{Output}(1)$ at the i-th server.
  2. Move to retrieval phase.

Phase 2. Retrieval

1. For all $j \in S_i^e$, invoke Retrieve on VID_j^e to download full block $B_j^{e\prime}$. Decompose $B_j^{e\prime}$ into transactions $T_j^{e\prime}$ and observation $V_j^{e\prime}$. Let $V_j^{e\prime} = [\infty, \infty, ..., \infty]$ if $B_j^{e\prime}$ is ill-formatted.
2. Deliver $\{T_j^{e\prime} | j \in S_i^e\}$ (sorted by increasing indices). Set $\text{Delivered}[e][j] = 1$ (initially 0) for all $j \in S_i^e$.
3. For $1 \le j \le n$, let $E_i^e[j]$ be the $(f+1)^{th}$-largest value among $\{V_k^{e\prime}[j] | k \in S_i^e\}$.
4. For all $1 \le j \le N$, for all $1 \le d \le E_i^e[j]$, check if $\text{Delivered}[d][j] = 0$. If so, invoke Retrieve on VID_j^d to download full block $B_j^{d\prime}$, and set $\text{Delivered}[d][j] = 1$ (initially 0).
5. Deliver all blocks downloaded in step 4 (sorted by increasing epoch number and node index).

Figure 17: Algorithm for DispersedLedger with inter-node linking. The blue color indicates the changes from the single-epoch algorithm.

So $\text{MerkleRoot}(\text{Encode}(B)) = \text{MerkleRoot}(\text{Encode}(B'))$ This contradicts with our assumption, so the assumption must not hold, and $B = B'$. □

C Specification of the full DispersedLedger protocol with Inter-node Linking

Figure 17 describes how to modify the single-epoch protocol to use inter-node linking. Blue color highlights the parts are added compared to the single-epoch protocol.

D Correctness proof of DispersedLedger

Notations. Let H ($H \subset \{1,2,...,N\}$) be the set of the indices of correct nodes. That is, $i \in H$ if and only if the i-th node is correct. In our proof, we use the variables in the full algorithm defined in Fig. 17. We also use "phase x, step y" to refer to specific steps in Fig. 17.

Lemma D.1. *For any epoch e, any $i \in H$, and any $1 \le j \le N$, if $j \in S_i^e$ then VID_i^e has Completed at some correct node.*

Proof. By the definition of S_i^e (phase 1, step 3), $j \in S_i^e$ if and only if BA_j^e has $\text{Output}(1)$ at the i-th node. By the Validity property of BA (§4.1), BA_j^e $\text{Output}(1)$ at a correct node implies that at least one correct node has invoked $\text{Input}(1)$ on BA_j^e, which only happens when that node sees VID_j^e Complete (phase 1, step 3). □

Lemma D.2. *For any epoch e, any $i, j \in H$, $S_i^e = S_j^e$ and $E_i^e = E_j^e$.*

Proof. By the definition of S_i^e (phase 1, step 3), $k \in S_i^e$ if and only if BA_k^e has $\text{Output}(1)$ at the i-th node. By the Agreement property of BA (§4.1), BA_k^e will eventually $\text{Output}(1)$ at the j-th node. So $k \in S_i^e$ if and only if $k \in S_j^e$, and $S_i^e = S_j^e$.

We now prove $E_i^e = E_j^e$. The i-th node (which is correct) starts the computation of E_i^e by invoking Retrieve on all VIDs in $\{\text{VID}_k^e | k \in S_i^e\}$. These Retrieves are guaranteed to finish by Lemma D.1 and the Availability property of VID (Theorem B.6). The node then extracts the observations $\{V_k^{e\prime} | k \in S_i^e\}$ from the downloaded blocks. Note that the j-th node will download the same set of observations. This is because $S_i^e = S_j^e$, and the VID Correctness property (Theorem B.9) guarantees the j-th node will obtain the same blocks when invoking Retrieve on $\{\text{VID}_k^e | k \in S_j^e\}$.

To combine the observations into the estimation, the i-th node runs phase 2, step 3. This process is deterministic, with E_i^e being a function of the observations $\{V_k^{e\prime} | k \in S_i^e\}$ and parameter f. Because we have just proved the j-th node will obtain the same set of estimations, and by our security model f is a protocol parameter known to all nodes (§2.4), the j-th node will get the same results.

□

Lemma D.3. *For any epoch e, and any $i \in H$, $|S_i^e| \ge N - f$. That is, S_i^e contains at least $N-f$ indices.*

Proof. By the definition of S_i^e (phase 1, step 3), this lemma essentially states that at least $N - f$ BAs among $\{\text{BA}_1^e, \text{BA}_2^e, ..., \text{BA}_N^e\}$ will $\text{Output}(1)$ at the i-th node.

Assume for contradiction that $|S_i^e| < N - f$. By Lemma D.2, $|S_j^e| < N - f$ for all $j \in H$, i.e., less than $N - f$ BAs eventually $\text{Output}(1)$ at every correct node. We now consider the possible outcomes of the remaining BA instances, which do not eventually $\text{Output}(1)$.

One possibility is some of them $\text{Output}(0)$. According to phase 1, step 3, correct nodes will not invoke $\text{Input}(0)$ on any BA instance unless $N - f$ BA instances have $\text{Output}(1)$. By our assumption, less than $N - f$ BA $\text{Output}(1)$, so the latter is not happening and *no* correct nodes will $\text{Input}(0)$ on *any* BA instance. By the Validity property of BA (§4.1), no BA instance can $\text{Output}(0)$.

We have showed that the remaining BAs cannot $\text{Output}(0)$, so it must be that all of them never terminate. We will prove it is also impossible. Assume for contradiction that all BAs that do not $\text{Output}(1)$ never terminate. By our assumption,

less than $N-f$ BAs $\texttt{Output}(1)$, so there must exist $k \in H$ such that $\texttt{BA}_k^e$ never terminates. By the Termination property of VID (Theorem B.2), $\texttt{VID}_k^e$ eventually $\texttt{Completes}$ on all correct nodes. According to phase 1, step 3, because not all BAs will terminate, all correct nodes will stay at this step. All correct nodes will $\texttt{Input}(1)$ to $\texttt{BA}_k^e$ upon seeing $\texttt{VID}_k^e$ $\texttt{Complete}$. By the Termination and Validity properties of BA (§4.1), $\texttt{BA}_k^e$ will terminate and $\texttt{Output}(1)$, which conflicts with our assumption.

We have showed there is no valid outcome for the remaining BA instances, so our assumption cannot hold, and at least $N-f$ BA instances eventually $\texttt{Output}(1)$ at all correct nodes. $\qquad \square$

Lemma D.4. *For any epoch e, any $i \in H$, and any $1 \leq j \leq N$, there exist $p,q \in H$ such that $V_p^e[j] \leq E_i^e[j] \leq V_q^e[j]$.*

Proof. The lemma states that if the i-th node (which is correct) computes the estimation $E_i^e[j]$ for the j-th node, then the estimation is lower- and upper-bounded by the *observations* $V_p^e[j]$ and $V_q^e[j]$ of two correct nodes (with indices p and q). That is, the estimation is not too high or too low.

Now assume for contradiction that for some $1 \leq j \leq N$, for all $p \in H$, $V_p^e[j] > E_i^e[j]$. That is, the estimation for j is not lower bounded by the observations made by any correct node. According to phase 2, step 3, the i-th node sets $E_i^e[j]$ to the $(f+1)^{th}$-largest value among $\{V_k^{e\prime}[j]|k \in S_i^e\}$. Here, $V_k^{e\prime}$ is the observation of the k-th node downloaded by invoking $\texttt{Retrieve}$ on $\texttt{VID}_k^e$. By Lemma D.1 and VID Availability property (Theorem B.6), the $\texttt{Retrieves}$ will eventually finish.

By our assumption, for all $p \in H \cap S_i^e$, $V_p^e[j] > E_i^e[j]$. By the VID Correctness property (Theorem B.9), the observations of correct nodes will be correctly downloaded. That is, $V_k^{e\prime} = V_k^e$ for all $k \in H$. So for all $p \in H \cap S_i^e$, $V_p^{e\prime}[j] > E_i^e[j]$. By Lemma D.3, $|S_i^e| \geq N-f$, so $|H \cap S_i^e| \geq N-2f$. So there are *at least* $N-2f$ values in $\{V_k^{e\prime}[j]|k \in S_i^e\}$ that are greater than $E_i^e[j]$. However, $E_i^e[j]$ is the $(f+1)^{th}$-largest value among $\{V_k^{e\prime}[j]|k \in S_i^e\}$, so there can be *at most* f values in $\{V_k^{e\prime}[j]|k \in S_i^e\}$ that are greater than $E_i^e[j]$. Because $N > 3f$ (§2.4), $N-2f > f$, so the two conclusions are in conflict, and the assumption cannot hold.

We can similarly prove it is impossible that for some $1 \leq j \leq N$, for all $q \in H$, $V_q^e[j] < E_i^e[j]$. $\qquad \square$

Theorem D.5 (DispersedLedger is well-defined). *For any epoch e, any $i \in H$, the i-th node eventually finishes epoch e.*

Proof. This lemma states that correct nodes will never be stuck in any epoch e, so that our algorithm is well-defined. To prove that, we go through Fig. 17 line by line and prove each step will eventually finish.

Phase 1, steps 1–2. These are local computation and will finish instantly.

Phase 1, step 3. This step finishes as soon as all BA instances in that epoch $\texttt{Output}$. By Lemma D.3, all correct nodes eventually see at least $N-f$ BA instances $\texttt{Output}(1)$. At that point, each correct node will invoke $\texttt{Input}(0)$ into all BAs on which it has not invoked $\texttt{Input}$. This ensures that all correct nodes eventually invoke $\texttt{Input}$ on all BAs. By the Termination property of BA (§4.1), all BAs will eventually $\texttt{Output}$ on all correct nodes, which ensures this step will finish.

Phase 2, step 1. This step finishes as soon as $\texttt{Retrieves}$ on $\{\texttt{VID}_j^e|j \in S_i^e\}$ finish. By Lemma D.1, $\{\texttt{VID}_j^e|j \in S_i^e\}$ will $\texttt{Complete}$ on all correct nodes. Then by VID Availability property (Theorem B.6), the $\texttt{Retrieves}$ will finish.

Phase 2, steps 2–3. These are local computation and will finish instantly.

Phase 2, step 4. This step will finish if for all $1 \leq j \leq N$, for all $1 \leq d \leq E_i^e[j]$, $\texttt{Retrieve}$ of $\texttt{VID}_j^d$ finishes. By Lemma D.4, there exists $q \in H$ such that $V_q^e[j] \geq E_i^e[j]$, and the q-th node (which is correct) reports that $\texttt{VID}_j^t$ has $\texttt{Completed}$ for all $1 \leq t \leq V_q^e[j]$. By VID Availability property (Theorem B.6), the $\texttt{Retrieves}$ will eventually finish, so this step will finish.

Phase 2, steps 5. This is local computation and will finish instantly. $\qquad \square$

Theorem D.6 (Validity). *All blocks proposed by correct nodes are eventually delivered by all correct nodes.*

Proof. Assume the i-th node (which is correct) proposes block B_i^e in epoch e. The i-th node invokes $\texttt{Disperse}(B_i^e)$ on $\texttt{VID}_i^e$. By VID Termination property (Theorem B.2), eventually all correct nodes will see $\texttt{VID}_i^e$ $\texttt{Complete}$. So there must exist an epoch t where for all $j \in H$, $V_j^t[i] \geq e$. That is, in epoch t, all correct nodes report that the i-th node has at least dispersed into $\texttt{VID}_i^1$ to $\texttt{VID}_i^e$. By Lemma D.4, for all $j \in H$, $E_j^t[i] \geq e$. According to phase 2, steps 4–5, all correct nodes either have already delivered B_i^e in previous epochs, or will deliver B_i^e in epoch t. $\qquad \square$

Theorem D.7 (Agreement and Total Order). *Two correct nodes deliver the same sequence of blocks.*

Proof. Let $i,j \in H$. We prove this theorem by induction on the number of epochs the i-th and the j-th nodes have finished. In other words, we prove that for any $t \geq 0$, the i-th and the j-th nodes deliver the same sequence of blocks in the first t epochs.

Initial ($t = 0$). Both nodes have not delivered any block. So the hypothesis clearly holds in this situation.

Induction step. Assume our hypothesis holds for $t = e-1$ ($e \geq 1$). We now prove the hypothesis holds for $t = e$. We first show the two nodes commit the same sequence of blocks with BA. By Lemma D.2, $S_i^e = S_j^e$ and $E_i^e = E_j^e$. According to phase 2, step 1, both nodes will invoke $\texttt{Retrieve}$ on the same set of VIDs. By VID Correctness property (Theorem B.9), they will get the same set of blocks and deliver them in the same order in phase 2, step 2.

We now show the two nodes commit the same sequence of blocks with inter-node linking. The local variable $\texttt{Delivered}$

stores whether a node has delivered a block (phase 2, steps 2, 4). By the induction hypothesis, the two nodes have delivered the same sequence of blocks prior to epoch e, so the variable `Delivered` is the same on the two nodes. By Lemma D.2, $E_i^e = E_j^e$. So the two nodes will invoke `Retrieve` on the same set of VIDs in phase 2, step 4 and get the same set of blocks. Both nodes sort the blocks deterministically and deliver them in the same order in phase 2, step 5.

We have proved that the i-th and the j-th nodes deliver the same sequence of blocks in epoch e. By our induction hypothesis, they deliver the same sequence until epoch $e-1$. So they deliver the same sequence in the first e epochs. This completes the induction. $\qquad\square$

Re-architecting Traffic Analysis with *Neural* Network Interface Cards

Abstract

We present an approach to improve the scalability of online machine learning-based network traffic analysis. We first make the case to replace widely-used supervised machine learning models for network traffic analysis with *binary neural networks*. We then introduce **N**eural **N**etworks on the **NIC** (N3IC), a system that compiles binary neural network models into implementations that can be directly integrated in the data plane of SmartNICs. N3IC supports different hardware targets, and it generates data plane descriptions using both micro-C and P4 languages.

We implement and evaluate our solution using two use cases related to traffic identification and to anomaly detection. In both cases, N3IC provides up to a 100x lower classification latency, and 1.5-7x higher throughput than state-of-the-art software-based machine learning classification systems. This is achieved by running the entire traffic analysis pipeline within the data plane of the SmartNIC, thereby completely freeing the system's CPU from any related tasks, while forwarding traffic at line rate (40Gbps) on the target NICs. Encouraged by these results we finally present the design and FPGA-based prototype of a hardware primitive that adds binary neural network support to a NIC data plane. Our new primitive requires less than 1-2% of the logic and memory resources of a VirteX7 FPGA. We show through experimental evaluation that extending the NIC data plane enables more challenging use cases that require online traffic analysis to be performed in a few microseconds.

1 Introduction

Online traffic analysis is a fundamental building block in today's networks, as it enables traffic classification [2, 5, 14, 26], security [10, 25, 31] and application-specific traffic forwarding strategies [40]. The complexity of network traffic patterns and the use of encrypted communications are driving the widespread adoption of traffic analysis based on Machine-Leaning (ML), implemented on commodity servers [13]. However, it is challenging to meet the throughput and latency requirements of modern networks while performing ML-based traffic

analysis [47]. Current high-performance solutions use programmable network interface cards (NICs) [12, 29, 48] to offload parts of the traffic analysis (e.g., flow statistic collection [1, 3, 28]) directly in their data plane, while still performing machine learning inference on a separate executor, e.g., the host's CPU. Unfortunately, moving the collected flow statistics across sub-systems introduces an important bottleneck [30], forcing high throughput solutions to send collected data to the ML executor in batches, thus sensibly increasing the processing latency (§ 2).

Recognizing that running ML inference *within* the network data plane would avoid data movements and solve the issue, state-of-the-art solutions implement widely used techniques, i.e., Decision Trees and their ensembles (Random Forests), using match-action tables, which are available within a NIC data plane [8, 55]. However, these solutions rely on expensive TCAM memories, and fitting Decision Trees in match-action tables requires restricting their depth to a few levels, thus impacting their accuracy. More specifically, [55] reports a maximum of five levels implemented on the NetFPGA, while [8] supports only Decision Trees of depth four on the Barefoot Tofino. Therefore, currently, network operators have to compromise between throughput, latency, or accuracy.

In this paper, we propose a new approach that efficiently leverages programmable NICs' hardware (and can achieve high throughput and low latency) while maintaining comparable accuracy with respect to existing ML-based traffic-analysis solutions implemented in software. The key insight is to exploit binary neural networks (BNNs) [15], a recently-proposed ML model targeting battery-powered edge devices. We show that BNNs can provide better classification accuracy than Decision Trees and Random Forests on the tested traffic analysis tasks (§ 3). Importantly, BNNs use single bits to represent inputs and weights, which provides two critical properties: (i) they exhibit a very compact memory footprint even for larger models; (ii) unlike mainstream Deep Neural Networks (DNNs), BNNs require only simple operations such as XOR and population count. This enables the implementation of efficient BNNs executors in a NIC's data plane,
Figure 1: N3IC overview. Users provide a labeled dataset. N3IC uses it to generate a binary neural network model, which is then compiled to a data plane program for a target NIC.

without requiring expensive resources, such as TCAMs.

Building on this insight, we developed N3IC, a complete solution to perform network traffic analysis using BNNs with commodity programmable NICs. N3IC comprises two key components (Figure 1, § 4): ① a framework to train a BNN using a labeled dataset provided by the user, and ② a compiler that translates the trained model into target-specific executable code. To show the generality of our approach, we implement two compiler backends: one targeting micro-C, a subset of the C language used by Netronome SoC-based NICs [29], and one targeting the P4 language [6]. The latter enables compiling to a growing set of P4-enabled NICs [21], including FPGA-based NICs using the P4->NetFPGA toolchain [16].

Furthermore, we evaluate the cost of providing BNN execution as a *native* hardware primitive that can be exposed to high-level programming languages (e.g., using P4's *extern*). We prototype this on the NetFPGA using RTL description language and show it only needs a modest 1-2% of a Xilinx Virtex7 FPGA's logic resources. While prior work has shown the potential of implementing ML models on FPGA [24, 51], they target ML models for application-level data processing, which has millisecond-scale latency requirements (as opposed to microsecond), and they are typically based on FPGA monolithic implementations. To the best of our knowledge, we are the first ones integrating a streamlined BNN executor, tailored to network traffic analysis models, *within* the NIC data plane.

We evaluate N3IC across different hardware platforms using traffic classification, security anomaly detection and network tomography as use cases (§ 6). Results show that N3IC can perform traffic analysis with high accuracy and with la-

tency in the microseconds, for millions of network flows per second, while processing packets at NICs' line rate. Compared to a similar system that implements the traffic analysis on a general-purpose CPU (with packet forwarding and feature extraction still offloaded to the NIC), N3IC provides up to 7x higher throughput and up to 100x lower latency.

Contributions. In this paper, we:

- demonstrate that BNNs provide high accuracy and low memory footprint for the selected traffic analysis use cases.
- design and implement an end-to-end system that performs traffic analysis in programmable NICs' data plane: this includes a framework to train BNNs and a compiler that translates models into both P4 and Netronome's micro-C.
- develop a new hardware primitive that enables BNN inference as first-class-primitive for next-generation programmable NICs.
- evaluate our solution on three traffic analysis use cases: (i) traffic classification, (ii) anomaly detection, and (iii) network tomography.
- Source code to reproduce key results of our work is at: https://github.com/nec-research/n3ic-nsdi22

2 Motivation and Challenges

Motivation. Modern data-center networks comprise a variety of network appliances, e.g., traffic classifiers, load balancers, and security middleboxes [34, 36]. They need to handle over a million of flows per second while only incurring a few tens of microseconds of processing latency per packet to avoid affecting the end-to-end latency [11, 23].

To meet these tight requirements, mainstream systems offload the packet capture and feature extraction steps to a programmable NIC [1, 28]. Periodically, the host system polls the extracted features from the NIC, and performs the analysis step. This approach relieves the load on the host's CPU and achieves higher throughput but at the cost of higher processing latency. To illustrate this trade-off in practice, we set up an experiment in which we offload the feature extraction on the Netronome NFP4000 NIC while we execute the analysis on an Intel E5-1630 v3 CPU. The results in Figure 2 (*NIC+CPU* line) show that as the throughput increases, the processing latency scales super-linearly. For instance, at 0.2M flows per second, the latency is 42μs but if we increase the throughput to 1M flows per second, the latency grows beyond 800μs.

There are two reasons for this. First, having the feature extraction and analysis steps running on two different subsystems requires moving data, e.g. crossing the PCIe bus, which can take up to a few microseconds [30]. Second, and most critically, CPUs require input data batching to improve the per-core processing efficiency. Batching improves data locality, avoiding stalls in the CPU pipeline due to data read delay, and it allows to fill the CPU's vector processing registers, thereby increasing the overall throughput but at the expense of much higher latency. This trade-off also applies to GPUs, which extensively rely on batching to achieve high through-
Figure 2: Processing latency when increasing throughput (flows per second) for a baseline performing feature extraction on the NIC and analysis on the CPU (*NIC+CPU*) and our system `N3IC`.

Figure 3: Forwarding throughput on a Netronome NFP4000 NIC, for different packet sizes when increasing the number of operations per packet.

put, and it explains why even network-attached GPUs [32] are not well-suited for low-latency packet processing.

A way to address the above issues is to perform the analysis directly within the subsystem that collects the data to be analyzed, i.e., within the NIC data plane. This would allows us to *(i)* avoid data movements from one subsystem to the other, and *(ii)* leverage the architectures of programmable NICs tailored to perform latency-efficient per-packet processing. As we detail in the rest of the paper, this indeed enables maintaining low latency (<40us) even at high throughput, as shown by the performance of `N3IC` in Figure 2.

Challenges. Existing solutions advocating for performing ML inference in the data plane of packet-processing hardware [8, 55] strictly rely on match-action tables that support ternary-matching. These resources are *(i)* not always available in a NIC data plane; *(ii)* costly, when available, since they use ternary content-addressable memory (TCAM), which is about 6x more expensive in terms of silicon area than SRAM [7]; *(iii)* limited; thus enabling only Decision Trees with small depth with an impact on the inference accuracy.[1] While using exact-matching tables may be a workaround, it would require enumerating the values to match on. For instance, to handle a single 16b feature, we may need to add 65k entries.

Enabling ML inference without the use of match-action tables resources and doing so while guaranteeing high-throughput, low latency, and high-accuracy requires solving three key challenges. First, existing programmable NICs have at most few 10s of MBs of fast on-chip SRAM memory [29, 48, 49]. Most of this memory, though, is needed to store forwarding and policy tables, leaving little space available for application data. This makes it hard to implement ML models within the NIC, often requiring trading-off model complexity for memory utilization. Second, to achieve high throughput the application logic needs to be highly parallelizable in order to fully utilize all compute resources on a NIC.

---

[1] Both IISY [55] and pforest [8] report an ability to run Decision Tree models with depth capped to five and four layers, respectively.

In fact, the NIC may provide a good amount of available processing resources if its architecture parallelism is leveraged. We show this in Figure 3, which plots the throughput achieved on the Netronome NFP4000 SmartNIC for different packet sizes as we increase the number of operations performed per packet. The larger the average packet size (and, hence, the less packets per second need to be processed), the higher is the number of operations that can be performed, before the forwarding throughput is negatively impacted. Finally, some ML models require complex arithmetic functions, such as multiplications or floating-point operations, which usually are not available on programmable NICs [45]. This limitation does not only affect the implementation of the ML model, but it also impacts the ability to perform pre-processing on the input features, as required by some models such as Support-Vector-Machine or K-Nearest-Neighbor.

3 Traffic Analysis with BNN

In this section, we show that binary neural networks (BNNs) are a promising option to address these challenges. Originally proposed for energy-efficient image processing on battery-powered devices, BNNs are an extreme quantized version of traditional DNNs in which each weight is encoded in just one bit rather than the typical 8-, 16- or 32-bit values. This makes them particularly appealing for our goals due to the following reasons. First, the single-bit input and weights drastically reduce their memory footprint. Second, the BNN's neurons perform a XOR between the input and weight vectors, and use as activation function the sign function on the population count (`popcnt`) performed on the bit vector resulting from the XOR. Therefore, they can be implemented efficiently (and with high performance) in hardware since XOR and `popcnt` operations are commonly supported by most platforms.

Unsurprisingly, for complex tasks such as image recognition, BNNs exhibit 3-10% points lower prediction accuracy than fully-fledged DNNs [20]. However, as we illustrate in the rest of this section, network traffic analysis models are usually much simpler and this enables BNNs to achieve an accuracy comparable (if not better) than existing implementations relying on decision trees and random forests.

3.1 Use cases

We introduce two typical traffic analysis uses cases that we use as running examples throughout the paper: IoT Traffic Classification and Security Anomaly Detection. Both use cases are general machine learning classification tasks, and therefore they are representative of common analysis use cases performed on network traffic. Further, they have open datasets, which helps making our results reproducible.

IoT Traffic Classification assigns an IoT device type to an observed network flow. For instance, this can be used in edge networks by operators to assign IoT traffic to specific Quality-of-Service classes. We focus on a 10-classes classification
Figure 4: The binary input vector is a concatenation of features' binary encodings. Each feature is represented using the minimum required number of bits to represent its values range. The number of bits per feature has to be fixed at training time.

task, where each flow is assigned to 9 possible device categories, such as home assistants, IoT cameras, sensors, or to a 10-th class that includes *anything else*, e.g., smartphones or laptops network traffic. We use 17 flow-level features to perform the classification. Examples of features are the number of packets and bytes being transferred, the mean packet interarrival time or the mean packet sizes. We remark that the selected features are not specific to this use case: they are widely supported in open source tools and used in production settings [35]. We use the dataset published by [44].

Security Anomaly Detection is about flagging network flows that are related to security issues, such as Denial-of-Service attacks, port scans, etc. This is a network analysis task widely applied in networks of any size, and in different scenarios including telecom operators networks, datacenters, and enterprises. For this task, flows are classified into two classes, i.e., good or bad. Usually, this kind of classification is used to potentially trigger more expensive downstream analysis on the traffic, and it has the goal to capture the large bulk of potentially malicious network interactions, rather than guaranteeing complete protection. For this task, in addition to the 17 flow-level features reported earlier, we add 3 additional features that look at the behavior of multiple flows. For instance, we consider the number of flows from a single source IP address. Like in the previous case, these features are well-known and widely adopted in operational settings. We use the dataset published by [27].

3.2 BNN Analysis Pipeline

To apply BNNs, we have to define the input features quantization strategy, to convert float and integer numbers into BNN's binary features. Then, we perform the training of the binary neural network using the labeled dataset. Finally, we evaluate the classification performance with previously unseen data.

Input preparation Previous work on BNNs introduces a first regular non-binary network layer that is trained together with the remaining binarized layers. This enables "learning" the quantization strategy for the features, but at the same time, it introduces multiplication operations within the first layer. We cannot afford to perform such operations in the data plane. Therefore, we designed a different quantization approach (Fig-

ure 4): we use as input to the BNN the concatenation of the flow feature values' binary representations. For instance, an input feature in the range 0-255 can be represented by an 8b vector. Our approach has two advantages: it does not require any additional processing since we reuse the hardware representation of the features; and it allows to assign to the features the number of bits their value ranges require. For instance, a single vector of 64b can be used to represent 4 features on 16b, or 3 features on 16b and 2 features on 8b; and so on.

BNN Training Like other ML models, BNNs need to be trained offline on a training dataset, in order to define the values of the weights that will be used during the online analysis phase. We perform training using the technique from Courbariaux and Bengio [9], which is based on a canonical back-propagation algorithm. This solution trains the network using float values, but it ensures that the BNN's weights converge to values included in the [-1, 1] range, and that they are normally distributed around 0. This helps in reducing the loss of information when the float weight values are mapped to just two values, i.e., 0 and 1 [9].

BNN traffic analysis performance We test three different BNNs architectures, each with 256 input binary features and three fully-connected layers. The three models differ by the number of neurons in the hidden layers: [32, 16, 10]; [64, 32, 10]; [128, 64, 10]. For both datasets, we use a 256b input vector. Although we have 17 and 20 features for the two cases, respectively, we can represent different number of features with the same binary input vector size by changing the number of bits used to represent each feature, as mentioned earlier (cf. Figure 4). We compare the BNNs to Decision Trees (DT) and Random Forests (RFs). For DTs, we vary the depth of the tree, between 3 and 10. RFs are an ensemble of DTs, therefore they have as an additional hyperparameter the number of trees, which we vary between 3 and 5. For readability, since the trends are similar, we only plot a subset of the results in the figures, i.e., three depth values of 3, 6, and 9, and always 5 trees for the RF. In all the tests, we perform 5-fold cross-validation, and report averaged results.[2]

In Figure 5 and Figure 6 we plot the classification accuracy vs the amount of memory required by the ML models, for the IoT and Security use cases, respectively. In the top plots, we do not make distinction between memory of type SRAM, used by BNN implementations, and of type TCAM, required by DT and RF implementations. Here, we can observe that the two larger BNNs achieve an accuracy that is closer to that of DTs and RFs of at least depth 6. The two larger BNNs achieve 96% and 97.4% using 2.5KB and 5.5KB of SRAM, vs 97% and 96.9% accuracy of DT6 and RF6, using 1.3KB and 6.4KB of TCAM, respectively. The smaller BNN achieves 92.4% accuracy using 1.2KB of SRAM. In the Security dataset, the classification is harder, and only the

---

[2]The IoT dataset is balanced across the 10 classification categories, with each category having 43k distinct flows. In the Security dataset, we have a binary classification with 164k anomalous and 90k normal flows.

Figure 6: Accuracy vs Memory (bytes) scatter plot for DT and RF on the Security dataset. BNNs always use SRAM-based implementations. DTs and RFs use TCAM (top) and SRAM (bottom) implementations.
Figure 7: F1 score (top) and FPR (bottom) of BNN models on the IoT dataset, compared to DTs and RFs.

Figure 8: F1 score (top) and FPR (bottom) of BNN models on the Security dataset, compared to DTs and RFs

larger DT9 and RF9 achieve accuracy above 90%, using respectively 3.4KB and 16.9KB of TCAM. The smallest BNN achieves 91.1% accuracy using just 1.2KB of SRAM. However, it should be noted that ternary matching with TCAM is roughly 6x more expensive than binary matching with SRAM, in terms of required silicon resources [7] and TCAM is often not available on NICs.

SRAM implementations: To compare the memory requirements when targeting similar hardware, in the bottom plots of Figure 5 and Figure 6 we show the memory consumption of DTs and RFs when using SRAM-based implementations. As described in [55], in the absence of TCAM support from the hardware target, all the values of the features selected by model fitting have to be enumerated as appearing in the data. Given that some of our features are flow statistics, the values they can potentially assume range from the minimum to the maximum observed from the data. In fact the memory requirements for DTs and RFs grow orders of magnitude larger (in this case, the plots have the x axis in log scale). Even the smallest DT3 model requires at least 40.2KB of SRAM for the IoT case, and 173.3KB for the Security case.

F1-score and FPR: We now look more carefully at the classifier performance, reporting F1-score and False Positive Rate (FPR) for the tested models. The F1-score is a harmonic mean of Precision and Recall, whereas the False Positive Rate tells the quota of negative samples mis-classified as positive, in a two-classes classifier. For this metric, in the IoT case that has 10 classes, we use a 1-vs-all strategy. The BNN models achieve always better F1-score when compared to the smallest DT and RF models, in both use cases. For larger models, the F1-score is in the range 88-91.6 in all cases, showing
relatively small variations among classifiers.

For the FPR, it is important to consider this metric in relation to the *Recall* of the classifier. In fact, a low FPR may be a symptom of a classifier assigning very few samples to the positive class. We can see this in Figure 7. DT3 and RF3 appear to have a relatively good FPR (3.0% and 2.1%). However, these low FPRs are due to the classifiers inability to identify the positive class. In particular, as captured also by F1-scores, DT3 and RF3 have a low Recall of 73.1% and 81.5% for the IoT case, whereas the smallest BNN has Recall at 92.4% with an FPR of 0.8%. We can see a similar issue in the Security use case (Figure 8). For instance, DT6 has FPR at 5.9% but Recall at 88.2%, whereas the smallest BNN has a higher FPR of 15.9% with a better Recall at 95.1%. Here, it should be noted that in this use case a reasonably higher FPR is not necessarily an issue. The anomaly detection is often used as a filter, before performing more expensive analysis on the flows classified as suspicious, e.g., diverting the traffic to a Scrubbing Center [33]. We provide more results in Appendix.

4 System design and implementation

We now present the design and implementation of N3IC, our end-to-end solution that enables to perform traffic analysis within a NIC data plane using BNNs (cf. Figure 1).

N3IC operations N3IC takes a training labeled dataset as input, and outputs programs that can be integrated into a target device's data plane. Currently, we support outputs in micro-C and P4 languages, targeting SoC-based Netronome SmartNICs and PISA-based architectures, respectively. N3IC entirely automates the generation of the BNN model and its implementation in the target data plane programming language. However, programmers need to perform the final integration step, to connect the input features extracted from the network packets with the programs generated by N3IC. In fact, feature extraction may happen in different ways, and

Figure 9: The architecture of a Netronome NFP4000's programmable blocks and the BNN processing with `N3IC`-NFP.

it is generally dependent on the implemented data plane features [3, 8]. Furthermore, since `N3IC` leverages the same hardware in the switching chips' data plane used also for other tasks, the networking and traffic analysis functionality can usually be intertwined, e.g., in the case of programs targeting the PISA architecture the same pipeline stages may take forwarding decisions and compute BNN's neurons. This is a process that in the future may be automated too, as data plane composability technology matures [46].

BNN model generation We described in § 3 the input feature quantization and training processes for BNNs. `N3IC` applies these processes on the provided labeled dataset. For input quantization, `N3IC` takes *hints* from the programmer, who can provide the number of bits that should be used to represent each feature. For instance, the programmer may have expert knowledge about what value ranges a given feature may have. Otherwise, `N3IC` can perform an automatic assignment of features to the binary input features vector, using the range of values observed in the dataset as a guide. Once the feature quantization strategy is fixed, `N3IC` starts a model search task. During this task several models are trained, and their performance on the provided data set is tested using K-fold cross validation. Also in this case the programmer can guide the process, providing a list of models to test or limitations on the maximum model size. Our current implementation performs a simple exhaustive search over a predefined (or programmer-provided) set of models, however, this step can also be enhanced with techniques that implement more sophisticated ML architecture search solutions [38].

At the end of these two steps, `N3IC` generates a BNN model implementing an MLP architecture, described by the number of layers, number of neurons per layer, and the corresponding weights. This description is finally passed to the target-specific BNN compilers, which generate the data plane programs that implement the BNN executors. We describe these implementations next.

4.1 SoC NIC: Netronome NFP4000

The NFP4000 architecture, shown in Figure 9, comprises tens of independent processing cores, which in Netronome terminology are named micro-engines (MEs). MEs are programmed with a high-level language named *micro-C*, a C dialect. Each ME has 8 threads, which allow the system to efficiently hide memory access times, e.g., context switching

15       $tmp\_out \leftarrow 0$;
16   **end**
17 **end**

---

between threads as they process different packets. MEs are further organized in islands, and each island has two shared SRAM memory areas of 64KB and 256KB, called CLS and CTM, respectively. Generally, these memory areas are used to host data required for the processing of each network packet. Finally, the chip provides a memory area shared by all islands, the IMEM, of 4MB SRAM, and a memory subsystem that combines two 3MB SRAMs, used as cache, with larger DRAMs, called EMEMs. These larger memories generally host forwarding tables, access control lists, and flow counters. The BNN executor implementation has to share the MEs and memory resources with packet processing tasks, thus, it has to strike the right balance between the needs of quickly forwarding network packets and running BNN inference. For both processing tasks the main bottleneck is the memory access time. Therefore, selecting the memory area to store BNN's weights plays a major role in our design.

If the BNN is small, like in our cases, it is worth considering the fastest available on-chip memories, i.e., the CTM and CTS, with an access time of less than 100ns [29]. However, the CTM memory is usually dedicated to packet processing tasks, being the memory used by the NFP to store incoming packets and making them available to the MEs. Thus, using the CTM may impact packet processing and should be avoided. Because of this, our implementation loads the NN's weights at configuration time in the CLS memory. Then, to run the BNN, `N3IC` outputs a function that can be run within an ME's thread, and which performs Algorithm 1. This function implements the BNN executor, with input and weights packed in 32b integers (i.e., `block_size` is 32). As a consequence, multiple threads can perform BNN executions in

8 **end**

parallel (Figure 9), and it is up to the programmer to decide when and how many threads to use for the BNN execution.

For example, a typical implementation would have, at boot time, each of the MEs' threads registering itself to be notified of packets reception. The NFP takes care of distributing packets to threads on a per-flow basis. This is a standard approach when programming the NFP. Thus, whenever a new packet is received, the NFP copies its content in an island's CTM, and notifies one of the island's threads to start packet processing. The notified thread can perform regular packet processing tasks, such as parsing, counters update, forwarding table lookups. The programmer can include in this context a trigger condition to start the processing of the BNN executor, by calling the function provided by N3IC. An example of triggering condition is the the reception of a predefined number of packets for a given flow.

4.2   BNN->P4->NetFPGA

P4 [6] is a domain-specific, platform-agnostic language for the programming of packet processing functions. N3IC implements a compiler that transforms BNN descriptions into BNN executors described with P4, targeting a PISA architecture. In principle, a P4-based implementation allows us to separate the N3IC's BNN executors from the underlying hardware-specific details, thus it should make the executor portable to any PISA architecture. However, as we will discuss at the end of the section, the target hardware architecture has still an important impact on the final implementation.

Compiling BNN to P4. The NNtoP4 compiler takes as input the BNN description created by the model generation step, and generates $P4_{16}$ code for a generic P4 target based on the PISA architecture. PISA is a spatial forwarding pipeline architecture, with a number of match-action units (MAUs) in series. A packet header vector (PHV), containing both the input packet and metadata information, is passed through the MAUs to perform the programmed processing tasks. Each MAU combines a table memory structure, for quick lookups using the PHV fields, with arrays of ALUs that perform operations on such fields. The code generated by NNtoP4 imple-

Figure 10: The logical steps required to implement a BNN using a PISA architecture.

ments a function, on top of the PISA architecture, which reads the input value from the PHV, performs the NN execution and writes back to a PHV's field the result of the computation. The NN weights are stored in the MAUs' fast memories to enable runtime reconfiguration. The generated P4 code also includes headers definition, parser, de-parser and control blocks. The code can therefore be easily extended to integrate with any other required packet processing function.

The basic operations needed to implement Algorithm 1 are (1) XNOR, (2) popcount and (3) SIGN function. Executing a XNOR and a comparison (SIGN) is readily supported by the P4 language. Unfortunately, the popcount operation is not. The main issue is that its execution time depends on the input size, which makes popcount difficult to implement in networking hardware, and therefore not supported in the PISA architecture. To overcome this issue using only current P4 primitives, we adapted the solution proposed in [4] (Item 169), as shown in Algorithm 2. The idea is to implement the popcount by combining basic integer arithmetic and logic operations in a tree structure whose depth is dependent on the input size.[3] A tree structure can be easily pipelined, with the processing of different tree's levels assigned to different pipeline's stages, thus achieving pipeline-level parallelism.

Overall, the processing includes five steps, each one mapped to a logical pipeline stage, except for the popcount which requires multiple stages, depending on the input size (cf. Figure 10). First, the NN input is replicated in as many PHV fields as the number of neurons to exploit the parallel processing on multiple packet header fields. Specifically, this corresponds to an unrolling (or partial unrolling) of the first for cycle of Algorithm 1. Second, each field, containing a copy of the NN input, is XNORed with the corresponding weight. The resulting value is further duplicated to additional fields to implement the shift, AND and sum as described in Algorithm 2. The outcome of each popcount is then compared with a threshold to implement the SIGN function, whose result is the output of each neuron. Finally, the resulting bits, stored in one PHV field for each neuron, are folded together in a single field. Depending on the NN depth, NNtoP4 replicates and concatenates the described operations as many times as the number of layers to obtain the complete MLP execution.

For hardware targets, it is worth noticing that the PHV

[3]See [52], chapter 5, for a longer description of the algorithm.

Figure 11: Hardware design of the BNN Executor module.

size limits the number of neurons the pipeline can execute in parallel. This is due to the need to replicate the input in the PHV to enable parallelism at the MAU level.

Generating P4 code for the NetFPGA. The NetFPGA is a 4x10GbE FPGA NIC, incorporating a Xilinx Virtex-7 FPGA. We integrate `N3IC` in the reference NIC project provided with the NetFPGA-SUME code base. We used the P4->NetFPGA workflow [16] to port the generated target-independent P4 code to the NetFPGA platform. The P4->NetFPGA workflow is built upon the Xilinx P4-SDNet [54] compiler and the NetFPGA-SUME code base. It translates P4 code to Verilog, and integrates it within the NetFPGA pipeline.

The P4->NetFPGA workflow required several adaptations to the `NNtoP4` compiler, in order to meet the FPGA resources and timing constraints. First, the P4-SDNet compiler does not support `if statements` among the operations of a MAU. Thus, we replaced all the if statements required by the SIGN function using a combination of bitwise logic operations and masks. Second, MAUs use the CAM IP core from Xilinx to implement lookup tables, which restricts the maximum width size that can be used for each entry. Consequently, a maximum of 32B can be fetched from memory every time a table is called, limiting the number of neuron weights that could be loaded in parallel by each table. To overcome this issue we had to write the weights as constant values in the MAU's operations code, effectively trading the possibility to perform runtime reconfiguration with the ability to compute more neurons in parallel. Finally, P4-SDNet is capable of performing a large number of operations on a field in a single MAU. This is in contrast with ASIC targets, which are instead usually constrained to execute a single operation per MAU [45]. This allowed us to describe several steps of a BNN computation in a single MAU, thus reducing the number of MAUs required to implement the BNN computation.

5 Hardware support for BNNs

While `N3IC` can generate data plane programs that implement a BNN executor, a native support for BNNs could enable more challenging use cases. In this section, we present the implementation of a data plane's hardware primitive to run BNN, and an example of a use case that can benefit from it.

5.1 BNN inference primitive

BNN executors have been presented in the past, however, their implementations were more generally targeted to applications within devices dedicated to AI and ML workloads, e.g., cameras. Instead, our target is to design a BNN executor integrated within the data plane of a NIC. This changes the implementation constraints. Most notably, our executor targets smaller models, and it is designed to fetch input data from the internal data plane data buses. We target the NetFPGA prototyping platform, and design our BNN executor in HDL.

Figure 11 shows the architecture of our BNN executor. The module is composed of multiple blocks. Each of them performs the computation of a single NN layer, and can be parametrized providing the sizes n and m for the input and output vectors, respectively. Together, the blocks build a BNN Executor for specific BNN architectures. For instance, three of these blocks are required to build a 3 layers MLP. The NN layer weights are stored in the FPGA on-chip memories, i.e., Block RAM (BRAM). The BRAMs are organized as tables with a number of rows dependent on the number of neurons, and with a width of 256b. Each row can be read in 2 clock cycles and, depending on the size n of the input vector, can store one or multiple weights, e.g., 1x256b or 16x32b. The BRAMs are shared by all the blocks of a BNN module.

A single block is a pipeline of three stages. The first reads the weights from the BRAM and performs the XNOR with the input. The second performs the first step of the popcount. Here, we create Lookup-Tables (LTs) of 256 entries each, in order to associate one 8b integer (address) to the corresponding population count value. Each block has $n/8$ of these LTs. As a consequence, for a 256b input we create 32 LTs that operate in parallel. In the last stage, the LTs outputs are summed together, the sign function is applied on the final sum and its result is stored in one of the m bits of the output register. If multiple weights are placed in a single BRAM's row, the module performs the execution of several neurons in parallel.

5.2 Enabling more challenging use cases

The BNN inference primitive can enable more challenging applications that have very low processing latency requirements. To highlight this, we look at a recently presented network tomography solution: SIMON [14]. SIMON periodically sends probe packets to measure network path delays, and then it uses the collected delay measurements to infer congestion points and the size of the related queues. The analysis of probe delays is performed offline with neural networks (MLPs). The high processing latency only enables post-mortem analysis. Therefore, in its current implementation, SIMON cannot be used to create a measurement and control loop, i.e., for path selection. The probe periodicity defines the processing latency constraint and it depends on the fastest link speed [14]. For instance, probes have to be sent every 250µs and 100µs for 40Gb/s and 100Gb/s links, respectively. As a consequence, to work at modern datacenters' link speeds and in real-time, the
Figure 12: N3IC enables the real-time implementation of SIMON [14], using BNNs in the NIC to identify congested queue from probes' one-way delays. This can be used to implement new traffic steering policies in the data plane.
Figure 13: Box plot of the accuracies for the predicted queues in the network tomography use case. BNNs makes our approach practical while trading just a tiny amount of accuracy with respect to non-binarized NNs.

execution latency has to be lower than few tens of µs.

We tested the use case simulating a CLOS-like Fat Tree datacenter network with ns3 [50], using different link speeds and traffic workloads. Following the methodology suggested by [14], we split the problem of inferring queue sizes in multiple sub-problems, each targeting a subset of the queues. This allows us to run smaller MLPs on each of the NICs. Unlike SIMON, our approach does not infer the actual size of a queue, but it only infers which queues are bigger than given thresholds levels. This information is usually sufficient for the control plane to take a flow-steering decision (See Figure 12).

We implement SIMON with N3IC, providing as input features 19 probes' one-way delays per BNN. A NIC can run multiple BNNs, since each of them infers the congestion status of a specific queue. We show the accuracy of prediction for each of the network queues in Figure 13, comparing the BNNs accuracy to that of non-binarized neural networks. For a BNN with three layers and 128, 64, 2 neurons per layer, across all the queues of the simulated network, we achieve a median accuracy in predicting a congested queue above 92%, which is comparable with the non-binarized neural network accuracy. As we will see in § 6, the introduced BNN hardware primitive will enable running these BNNs within the processing latency required for links faster than 400Gb/s.

6 System-level Evaluation

In this section, we present the experimental evaluation of N3IC's BNN executors. We report and discuss the end-to-end performance of the use cases presented in § 3, and of the the network tomography use case from § 5. Furthermore, we report results for micro-benchmarks and resource requirements.

Testbed. Unless stated otherwise, the system-under-test (SuT) uses a machine equipped with an Intel Haswell E5-1630 v3 CPU and either a Netronome Agilio CX, with an NFP4000 processor, or a NetFPGA-SUME[4]. The Haswell is clocked at

---

[4]The Haswell CPU was produced with a 22nm factory process, i.e., a technology comparable to the NFP4000 (22nm) and NetFPGA Virtex7 (28nm).

3.7GHz, the NFP at 800MHz, and the NetFPGA at 200MHz for both the N3IC-P4 and N3IC-FPGA (i.e., using the hardware primitive) implementations. The host system runs Linux, kernel v.4.18.15. The SuT is connected back-to-back to a second machine that hosts the traffic generators and receivers. For stress tests, we use a 40Gb/s capable DPDK packet generator[5], and we use HTTP clients and ngnix as receiver, both hosted on the second machine. We always measure that the SuT is the performance bottleneck, ensuring that the setup achieves line-rate when removing the SuT from the loop.

Comparison term. We compared our prototypes with a traffic analysis system (bnn-exec) that performs feature extraction on the NIC and the analysis task in software, using binary neural networks like those employed by N3IC. bnn-exec is available at [43]. We wrote bnn-exec in C, and optimized it for the Haswell CPU, with some parts in assembler to take full advantage of the CPU's architecture features, such as AVX2 instructions. bnn-exec is faster than any other software BNN executor we tested, and performs the analysis task with performance comparable to that of optimized libraries for DTs and RFs [17]. We setup bnn-exec to read flows statistics/data from the Netronome NIC and ran bnn-exec only with the Netronome NIC since its driver is more mature than the NetFPGA's: it can better handle fast communication between the NIC and the host system. When performing analysis with bnn-exec we took into account (1) the time to read one or more flow statistics; (2) the time to run the BNN itself; and (3) the time to write back the result on the NIC. This allows us to perform a fair comparison against N3IC.

Feature extraction. Our end-to-end system need feature extraction to be implemented in the NIC's data plane.In fact, the quality of the inference tasks performed by the downstream ML model strictly depends on the quality of the extracted features. In some use cases, feature extraction may be simpler than in others. For instance, in the IoT use case the outcome of the inference task assigns flows to QoS classes. While a mis-classification is undesirable, its impact on the infrastructure is usually limited, and one may give priority to efficiency of implementation vs accuracy. Instead, in security use cases there may be a stricter need to ensure that feature extraction is robust, e.g., to protect against adversarial attacks [37].

For the tests in this section, we use two different state-of-the-art feature extraction strategies. In stress tests, we use a simpler approach that allows us to evaluate the N3IC implementations, ensuring that N3IC is the actual system bottleneck. In this case, the NIC stores the per-flow features in a hashtable, using the flow's 5-tuple as lookup key. When a packet is received, the corresponding flow's features are retrieved from the hashtable and updated. If the lookup produces a miss, the packet is considered as belonging to a new flow. Entries are removed from the hashtable lazily, if no packets for the corresponding flow are received in a given time window. In

Figure 14: For IoT and Security use cases, `N3IC` is 1.5x-7x faster than `bnn-exec`, while forwarding packets at 40Gb/s.

Figure 15: For IoT and Security use cases, `N3IC` implementations can provide at least 10-100x lower latency than `bnn-exec`.

Figure 16: `N3IC`-NFP throughput for the IoT use case when analyzing 500, 1k, and 10k parallel TCP flows.

Figure 17: `N3IC`-FPGA can support the network tomography use case even in fast 400Gb/s networks with probes sent every 25µs.

Figure 18: Maximum throughput in number of BNNs execution per second for `N3IC` BNN executors.

this approach, only the TCP's connection establishment is tracked, and no further connection tracking is performed.

In a second approach, we use a more complex solution performing full TCP-connection tracking. A connection tracking automaton validates that a received packet belongs to the 5-tuple flow (e.g., checking sequence numbers), before performing the features update as in the simpler approach. We used the TCP-connection tracking implementation of Flowblaze [36] that also allows us to change the behavior for sequence number checking, e.g., using either *window shifting* or *window advancing* solutions.

In both cases, we only track flow-level features. Collecting the 3 host-level features used in the Security use case requires more complex operations, which we did not implement since the impact of such features on the BNN classification accuracy is negligible (Cf. Appendix for a detailed report). Flow-level features can be: directly extracted from the packet headers (e.g. protocol number), computed by accumulating values extracted from packet headers (e.g, total transferred bytes) or derived from the calculation of flow level metrics (e.g. packet interarrival, mean flow size). In the latter case difference based metrics (e.g. flow duration) are computed for each packet in the flow, while mean based metrics are only partially computed (i.e. total and number of values are stored separately) per packet and then finalized (i.e. total/number) each time the feature is fed to the NN. Additional per flow values are stored in order to compute the flow level metrics (Table 4 in Appendix). The computation of the per-flow statistics is a memory-bound operation so the extra overhead due to the metric computation is negligible respect to the cost of accessing the flow tables. We implement the feature extraction strategies both in the Netronome NFP and in the NetFPGA, for which we report its resources consumption in Table 1. We refer to the two Feature Extraction (FE) strategies as *simple* FE and *advanced* FE, respectively.

6.1   End-to-end performance tests

In all the end-to-end tests, we measure the analysis throughput and latency, *while the system-under-test forwards network*

traffic at 40Gb/s within the NIC (NFP4000 or NetFPGA).

Traffic analysis use cases We perform two different tests to measure the end-to-end `N3IC` performance with the use cases from Section 3. First, we run a stress test generating a large number of small packets with the DPDK packet generator, then we perform a performance test with real TCP flows generated by HTTP clients and nginx. For the stress test, the provided traffic contains 1.8M flows per second.[6] This is a challenging load for a single server, being more common in ToR switches handling traffic for high throughput user-facing services [23]. If `N3IC` can meet this performance goal, it is likely to be capable of handling a large range of ordinary use cases. For the TCP tests, we vary the number of flows between 500 and 10k, and always generate 40Gb/s of traffic. *Baseline:* We measured the NIC performance when only collecting flow statistics with the simpler approach introduced earlier. The Netronome provides its 40Gb/s line rate only with packets of size 256B (18.1Mpps) or bigger. This is achieved using 90 out of the 480 available threads, and it is in line with the device's expected performance for such class of applications. In fact, the NFP can efficiently hide hash-table lookup latencies by distributing the processing on multiple threads, while consistently assigning flows to different threads. This avoids expensive locking of the hash-table, since different parallel executors do not access the same entry. The NetFPGA, instead, is capable of forwarding 40Gb/s with minimum size (64B) packets while collecting flow statistics, in any case. *Stress Tests:* We use the smaller BNN models reported in § 3 to test `N3IC` performance, since they achieve comparable accuracy with the larger DTs and RFs models. We summarized the throughput results in Figure 14. `N3IC` implementations can all achieve the offered throughput of 1.81M flow analysis/s. Instead, even if using larger batch sizes, `bnn-exec` is unable to cope with such load, when running on a single CPU core. `bnn-exec` maximum throughput is 1.18M analyzed flows/s, when using very large batches of 10K flows. More interestingly, Figure 15 shows that `N3IC` implementations provide also a low processing latency, with a 95-th percentile of 42µs

---

[6]That is, an average of 10 packets per flow at 40Gb/s@256B.

for `N3IC`-NFP, and only 2µs and 0.5µs for `N3IC`-P4 and `N3IC`-FPGA, respectively. In comparison, for `bnn-exec` to achieve a throughput above the 1M flows/s, the processing latency is 1ms and 8ms with batch sizes 1K and 10K, respectively.

TCP Test: we run an additional experiment, using the IoT application, to check the functionality of `N3IC` with flows generated by HTTP clients and *nginx*, when using the second feature extraction strategy with full TCP tracking. The HTTP clients generate 40Gb/s distributed among 500, 1k, and 10k parallel flows. Since TCP flows have larger average packet size (close to the maximum of 1.5KB), this corresponds to about 3.2Mpps at 40Gb/s line rate. We further instrument `N3IC` to perform inference on a flow after every (10, 100, 1000) received flow's packets. This corresponds to up to over 320k ML inferences per second. Figure 16 shows that `N3IC` can forward all the received packets, while collecting statistics and performing ML inference (we show only `N3IC`-NFP, and for inferences every 10 flow's packets, since results for the other experiments and for `N3IC`-FPGA are similar). An interesting observation is that the NFP's throughput does not change when adding `N3IC` inference load. This happens since feature extraction requires memory lookups, whereas BNN inference requires mostly processing power from the NFP's MEs, thus the two workloads can be efficiently co-located.

Network Tomography When testing the network tomography use case, the NIC stores the one-way-delay value for the received network probes, before passing them to the analysis engine, i.e., either `N3IC` or `bnn-exec`. Here, processing latency is the critical performance indicator. Figure 17 shows that `bnn-exec` provides a processing latency of about 40µs, which is within the budget of 100µs.[7] However, upcoming network links of 400Gb/s could not be supported, since they would lower the periodicity of the probes to 25µs. `N3IC` processing latency for SIMON's BNNs with 128, 64, 2 neurons is 170µs for `N3IC`-NFP and below 2µs for `N3IC`-FPGA. As we further clarify next, `N3IC`-P4 cannot scale to run larger BNNs, and can only run the smaller 32, 16, 2 neurons networks with about 2µs of delay, at the cost of reduced accuracy. For upcoming 400Gb/s network speeds, the BNN hardware primitive enables running more accurate BNN models, while being within the processing latency requirement.

6.2 Scalability tests

We now evaluate the processing throughput and latency when varying the size of the BNN. We performed this evaluation fully loading `N3IC`, and by executing a single BNN layer with 256 binary inputs. We varied the number of neurons to be 32, 64, and 128.[8] Figure 18 shows that the throughput decreases linearly with the layer's size for `N3IC`-NFP and `N3IC`-FPGA. Latency, instead, increases linearly (not shown). This is ex-

---

[7]In this case high-throughput is not required, so we use a batch size of 1.

[8]The layer is fully-connected, therefore its size is the number of input times the number of neurons: a layer with 128 neurons has 4KB of weights, i.e., about 4x the size of the NN used for the traffic analysis use cases.

Design	LUT		BRAM	
	#	% tot	#	% tot
Reference NIC (RN)	49.4k	11.4%	194	13.2%
RN + simple Feature Extraction (FE)	50.0k	11.56%	258	17.6%
RN + simple FE + `N3IC`-FGPA	52.6k	12.16%	275	18.8%
RN + simple FE + `N3IC`-P4	145.1k	33.56%	582	39.6%
RN + advanced FE	92.0k	21.56%	458	32.6%
RN + advanced FE + `N3IC`-FPGA	95.0k	22.86%	475	33.8%

Table 1: NetFPGA resources usage. `N3IC`-FPGA requires little additional resources. `N3IC`-P4 uses a large amount of NIC resources due to the PISA computation model constraints.

pected given the design presented in § 4. In comparison, `N3IC`-P4 throughput results are much higher for a layer with 32 and 64 neurons. Unfortunately, results for 128 neurons are missing, since `N3IC`-P4 could not scale to handle such layers. We provide more insight on this in the next subsection.

6.3 System resources usage

We quantify the resources needed by `N3IC`. Compared to state-of-the-art systems like `bnn-exec`, `N3IC` does NOT use any CPU cores and keeps the PCIe bus free. It does however use additional resources on the NIC. We evaluate this referring to the BNNs used in the traffic analysis use cases.

In the NFP case, `N3IC` has to store the NN's weights in the NFP4000's memory system. The NNs used with the traffic analysis use cases require 1.5% of the CLS memory, and 480 threads to face the offered load, instead of the 90 required to achieve line-rate throughput when the NIC is only collecting flow statistics. Here, it should be noted that it is possible to use less threads, if a performance drop in NN inference throughput is acceptable. For instance, using only 120 threads, i.e., 30 additional threads compared to the baseline, reduces the throughput of flows analyzed per second by 10x. This still provides the ability to analyze over 100k flows per second, which is sufficient for many workloads.

In the NetFPGA cases, we measured the hardware resources required to synthesize `N3IC` on the Virtex7 FPGA, and compare them to the standard NetFPGA reference NIC design's resources, including the resources required to implement the feature extraction logic. Table 1 summarizes the results. `N3IC`-FPGA requires only an additional 0.6% and 1.2% of the FPGA's LUTs and BRAMs, respectively. The resource consumption is so small since we included in the data plane a single BNN executor module, which was dimensioned to achieve the analysis throughput measured in the tests reported in this section. Instead, the `N3IC`-P4 implementation requires a relatively large amount of resources, with an additional 22% for both LUTs and BRAMs. For comparison, the implementation of DTs with depth 5 in the data plane reported in [55] requires 27% and 40% of LUTs and BRAMs, respectively. This is the case because the P4 implementation embeds the BNN executor within a PISA-like pipeline targeted by the P4->NetFPGA toolchain. That is, the computations of the BNN are unrolled to be distributed on multiple PISA's

match-action stages. While this has the effect of completely pipelining the BNN execution, it also requires using a large amount of FPGA resources. That is, like it is the case for other P4 programs using the P4->NetFPGA toolchain, with `N3IC`-P4 the successful compilation and synthesis of the P4 program guarantees the NIC's line rate during execution. Therefore, `N3IC`-P4 can run a BNN inference for each received packet and still match packet forwarding line rate (cf. Figure 18). For this reason, it should also be noted that in `N3IC`-P4 most of the resources can be reused to implement also regular packet forwarding, since the pipeline stages required by `N3IC` can host forwarding rules coming from other processing tasks.

7   Discussion

What are the limitations? Since `N3IC` BNNs run in the data plane, only features that can be computed/extracted within the data plane can be used as input. This limits the applicability of `N3IC` to devices that offer such functionality. For instance, porting `N3IC` to a switch's data plane may be limited by the availability of input features. For similar reasons, more complex models that require application-level data, e.g., payload of packets and with KBs of input size, are not well handled by `N3IC`. For these kind of analysis tasks, more relevant solutions may be previous work such as Brainwave [24] and Taurus [47], or some recently presented NICs that combine specialized executors for ML models, e.g., NVIDIA EGX A100 [32] and Xilinx Alveo SN1000 [53]. In fact, although these executors are not well suited for the low latency analysis tasks addressed by `N3IC` (cf. § 2), they are especially designed to perform complex algorithms on larger data, with processing latency in the ms.

Is it all about scalability and performance? While `N3IC` improves the performance of existing traffic analysis systems, we believe the ability to perform flow-level traffic analysis entirely in the NIC can provide a tool to rethink system architectures. For instance, the ability to track the queue status of network switches in near real time (§ 5.2) would make it practical the implementation of load-aware data center load balancing schemes that take decision from the end host [18], or it could enable new congestion control algorithms.

8   Related Work

Traffic analysis with machine learning is performed by systems in many operational settings [39], e.g., for traffic classification [2, 5, 14, 26, 40] and security [3, 10, 19, 25]. Some solutions scale traffic analysis performance using NICs [12, 29, 48] that have the ability to perform feature extraction (e.g., flow statistic collection [1, 3, 28]). Unlike these solutions, `N3IC` enables also the execution of machine learning-based analysis within the NIC's data plane. Previous work presented a similar idea when targeting switches [8, 55], and [8] covers also the issue of selecting the subset of features that can be efficiently collected within the data plane. In `N3IC` we leverage the flexibility of a NIC's data plane, designed to process

significantly less traffic than a switch, to relax this issue.

The idea of using binary neural networks within the network data plane was presented in some early works [41, 42]. [42] presents a conceptual design for RMT [7] switches. [41] targets end-host ML applications, in which the NIC works as a co-processor for Convolutional Neural Networks for image classification that runs on the host. We build on similar insights and extend those early ideas in many ways. First, we show the suitability of BNNs for traffic analysis use cases, comparing them with state-of-the-art ML techniques. Then, we present an end-to-end system design that builds BNN executors for different NIC architectures, starting from a labeled dataset. Finally, we present a complete evaluation of BNN executors on two NICs, propose a dedicated hardware-native implementation, and include an end-to-end evaluation of three networking use cases, with related trade-offs.

Finally, while not directly related to `N3IC`, recent work on the security of network applications that use machine learning is likely to influence developments in this area [22, 31].

9   Conclusion

We addressed the problem of improving throughput, latency, and efficiency of packet- and flow-level network traffic analysis, usually performed by software middleboxes and network functions. We first show that binary neural networks can replace widely-adopted decision trees and random forests, on the tested network traffic analysis tasks. Then, we make the case for implementing them in the data plane of commodity programmable NICs. We design and implement an end-to-end system composed of a binary neural network model generation module, and a compiler that generates data plane programs to execute the binary neural network model in the data plane of commodity programmable NICs (i.e., Netronome SmartNICs and P4-enabled NICs). Moreover, we also design and prototype a new hardware primitive that allows a NIC to perform BNN model execution directly. We evaluated our approach using two different NICs, Netronome NFP4000 and NetFPGA, and for a set of use cases representing a large variety of current traffic analysis applications, including traffic classification, anomaly detection and network tomography. Our results show that our system can accurately perform analyses for millions of flows per second, with low latency, while processing packets at NICs' line rates.

A Appendix

We provide additional details and test results about the tested machine learning (ML) models, and about the implementation of the BNN executors.

A.1 Input Features

Table 2 reports the set of features used by the IoT Traffic Classification use case to perform the classification, while Table 3 reports the ones used by the Security Anomaly Detection use case. It should be noted that all the features used by the former use case are also used by the latter. However, some of the features shared by the two use cases differ in the number of bits used for their binary encoding. For example, feature *dur* in the IoT use case requires twice the number of bits with respect to the Security use case.

For the Security use case, we tested the classification performance of the ML models with and without the host-based features. In fact, these features complicate significantly the feature extraction process on the NIC. As we will see in the next subsections, this impacts significantly the classification performance of Decision Trees, while it has minimal impact on BNNs. We speculate that this is the case since not only BNNs perform classification using all the available features, but they also naturally build intermediate features (i.e., feature engineering) in their hidden layers; whereas DTs and RFs use only a subset of the provided features. This observation suggests that there maybe more advantages in using BNNs, beyond those reported in the paper. E.g., BNNs may enable to perform inference using a set of features that are cheaper to collect. However, we leave more investigation into this for future studies, and therefore we only report that this is indeed the case for the Security use case.

Features number vs Memory requirements. Another aspect we did not discuss in the paper is the memory requirement associated with the features. This is usually a bigger issues in switching devices that deal with larger amounts of traffic, such as network switches and routers, while it is not a hard constraint in NICs that are provided with larger (per-flow) memories. In the use cases analyzed in the paper, we use a 256b feature vector, i.e., each flow entry has a memory occupation of 45B (13B for the flowkey, and 32B for the features). That is, a features table for e.g., 10K active flows needs less than 0.5MB of (SRAM) memory.

Feature extraction additional counters. Table 4 lists additional counters that are needed for the feature extraction. Indeed, in order to calculate duration and average input features, five per flow counters have to be stored. Timestamps of the flow start and the last packet sent by the source/destination are used to calculate: the duration of the flow (dur Table 2, 3), the average load (sload, dload), the interarrival times (sinpkt and dinpkt) and TCP connection setup time (ackdat, synack).

Feature	Description	Bin. enc. length
dur	record total duration	16
proto	transaction protocol	8
sbytes	src -> dst transaction bytes	24
bytes	dst -> src transaction bytes	24
sttl	src -> dst TTL value	8
dttl	dst -> src TTL value	8
sload	source bits per second	24
dload	destination bits per second	24
spkts	src -> dst packet count	16
dpkts	dst -> src packet count	16
smean	Mean of the flow packet size tx by the src	16
dmean	Mean of the flow packet size tx by the dst	16
sinpkt	source interpacket arrival time	16
dinpkt	destination interpacket arrival time	16
tcprtt	TCP connection setup round-trip time the sum, of 'synack' and 'ackdat'.	8
synack	TCP connection setup time, the time between, the SYN and the SYN_ACK packets	8
ackdat	TCP connection setup time, the time between the SYN_ACK and the ACK packets.	8

Table 2: IoT Traffic Classification input features

While the source/destination total packet counters are used only to calculate the mean flow size.

A.2 Machine Learning Models

A.2.1 Additional evaluation metrics

This section provides supplementary evaluation results to complement the F1-score and False Positive Rate (FPR) metrics presented in Section 3 of the paper. TP, TN, FP and FN indicate the True Positives, True Negatives, False Positives, and False Negatives, respectively. We report here the following metrics:

- Accuracy: computed as $(TP + TN)/(TP + TN + FP + FN)$, it quantifies the percentage of correct predictions.
- Precision (P): computed as $TP/(TP + FP)$, it quantifies the quota of positive class predictions that actually belong to the positive class.
- Recall (R) or True Positive Rate (TPR): computed as $TP/(TP + FN)$, it quantifies the quota of positive samples that are correctly predicted as positive.
- F1-score: computed as $2TP/(2TP + FP + FN)$, it is the harmonic mean of Precision and Recall.
- False Positive Rate (FPR): computed as $FP/(FP + TN)$, it quantifies the quota of negative samples that are wrongly predicted as positive.
- False Negative Rate (FNR): computed as $FN/(FN + TP)$, it quantifies the quota of positive samples that are wrongly predicted as negative.
- ROC-AUC: the Receiver Operating Characteristic (ROC) curve captures the TPR-FPR tradeoff at different classification thresholds. ROC-AUC is the area under the ROC curve and provides an aggregate measure to quantify the performance of a classification model across all the classification thresholds.

Feature	Description	Bin. enc. length
dur	record total duration	8
proto	transaction protocol	8
sbytes	src -> dst transaction bytes	16
bytes	dst -> src transaction bytes	16
sttl	src -> dst TTL value	8
dttl	dst -> src TTL value	8
sload	source bits per second	24
dload	destination bits per second	24
spkts	src -> dst packet count	16
dpkts	dst -> src packet count	16
smean	Mean of the flow packet size tx by the src	16
dmean	Mean of the flow packet size tx by the dst	16
sinpkt	source interpacket arrival time	16
dinpkt	destination interpacket arrival time	16
tcprtt	TCP connection setup round-trip time, the sum of 'synack' and 'ackdat'.	8
synack	TCP connection setup time, the time between the SYN and the SYN_ACK packets	8
ackdat	TCP connection setup time, the time between the SYN_ACK and the ACK packets	8
Host-based features		
ct_src_ltm	No. of connections of the same dst address in 100 connections according to the last time	8
ct_dst_ltm	No. of connections of the same src address in 100 connections according to the last time	8
ct_ds_src_ltm	No of connections of the same src/dst address in 100 connections according to the last time	8

Table 3: Security Anomaly Detection input features

Counter	Description
flow start	flow start timestamp
dst pkt count	Total number of packets sent by dst
src pkt count	Total number of packets sent by src
dts last pkt ts	Timestamp of the last pkt sent by dst
src last pkt ts	Timestamp of the last pkt sent by src

Table 4: Feature extraction additional counters

Here, we notice that the False Negative Rate (FNR) is not reported in the results, since it is computed as $FNR = 1 - Recall$, and we already report Recall for all the cases.

For each metric we report the average and standard deviation resulting from a 5-fold cross-validation. In the IoT case we are dealing with a 10-classes classification problem, thus, we used a one-vs-rest strategy to evaluate the False Positive and True Positive Rates. Following the description of Section 3, we focused on 3 representative configurations for each type of model. Specifically, for the Decision Tree (DT) and Random Forest (RF) models we considered tree depths values of 3, 6, and 9, and always 5 trees for the RF. The BNN models use a Multi-layer Perceptron architecture, with 256 input binary features and three fully-connected layers. The three models differ by the number of neurons in the hidden layers: [32, 16, n]; [64; 32; n]; [128, 64, n] where $n = 10$ for the IoT use case and $n = 2$ for the Security use case.

We also include two additional columns (TCAM and SRAM) reporting the memory consumption for the TCAM-based and SRAM-based implementations. In the case of BNNs, there is only an SRAM-based implementation, as re-

ported in the paper in Section 3.2.

The results for the IoT use cases are reported in Table 5, while Table 6 reports the results for the Security use case.

A.2.2 Security Anomaly Detection without host features

For the Security use case, as mentioned earlier, we also run the classifier tests to check that the implications of removing the three additional non-flow level features is minimal for the BNN accuracy: the three BNN models described in the paper (32,16,2; 64,32,2; 128,64,2) achieve accuracy [0.9114, 0.9162, 0.9198] when including the 3 extra features, and [0.9106, 0.9164, 0.9201] when not including them (a difference of at most 0.1% point). The results for Decision Trees and Random Forests are instead more impacted, as shown in Table 7.

A.2.3 Confusion Matrices

Figures 19 and 20 report the confusion matrices for the IoT Traffic Classification and Security Anomaly Detection (with all features) use cases, respectively. The matrices have been normalized by dividing the counts by the sum of each row. For each use case we selected a single fold for each of the 9 representative models. In the 3x3 grid, each row contains a different type of model, i.e. Decision Trees (DT), Random Forests (RF) and Binary Neural Networks (BNN). For a given row, different columns contain an increasingly more complex model of a same type, e.g. a more deep tree-based model or a MLP with a larger number of neurons in the hidden layers.

The confusion matrices in the IoT use case confirm that small DTs and RFs fail to properly classify samples belonging to some classes. This is also a byproduct of using binary-decision trees, which fail to identify all of the 10 classes when so shallow. Performance improves as the complexity of the model increases. BNNs are instead able to classify almost all the classes even in the smallest configuration.

A.3 In-NIC Feature Extraction

As mentioned in the Section 6 of the paper, we implement two different features extraction strategies in both the Netronome NIC and NetFPGA. We give more details about these implementations in this subsection.

In both cases, we leverage the modern NIC's ability to host a large number of flow entries (several 10ks) in memory. For instance, both the Netronome and the NetFPGA are also equipped with relatively large DRAMs that can be leveraged to host very large flow tables.

A.3.1 Feature Extraction without connection tracking

The simpler feature extraction strategy keeps a hashtable with the active flows, and performs the following operations, on packet reception: (i) packet parsing to extract the needed
Figure 19: Confusion Matrices for the IoT use case

information, including the 5-tuple used as lookup key; (ii) lookup in the hashtable to retrieve the corresponding flow counters; (iii) update of the values to account for the new packet reception.

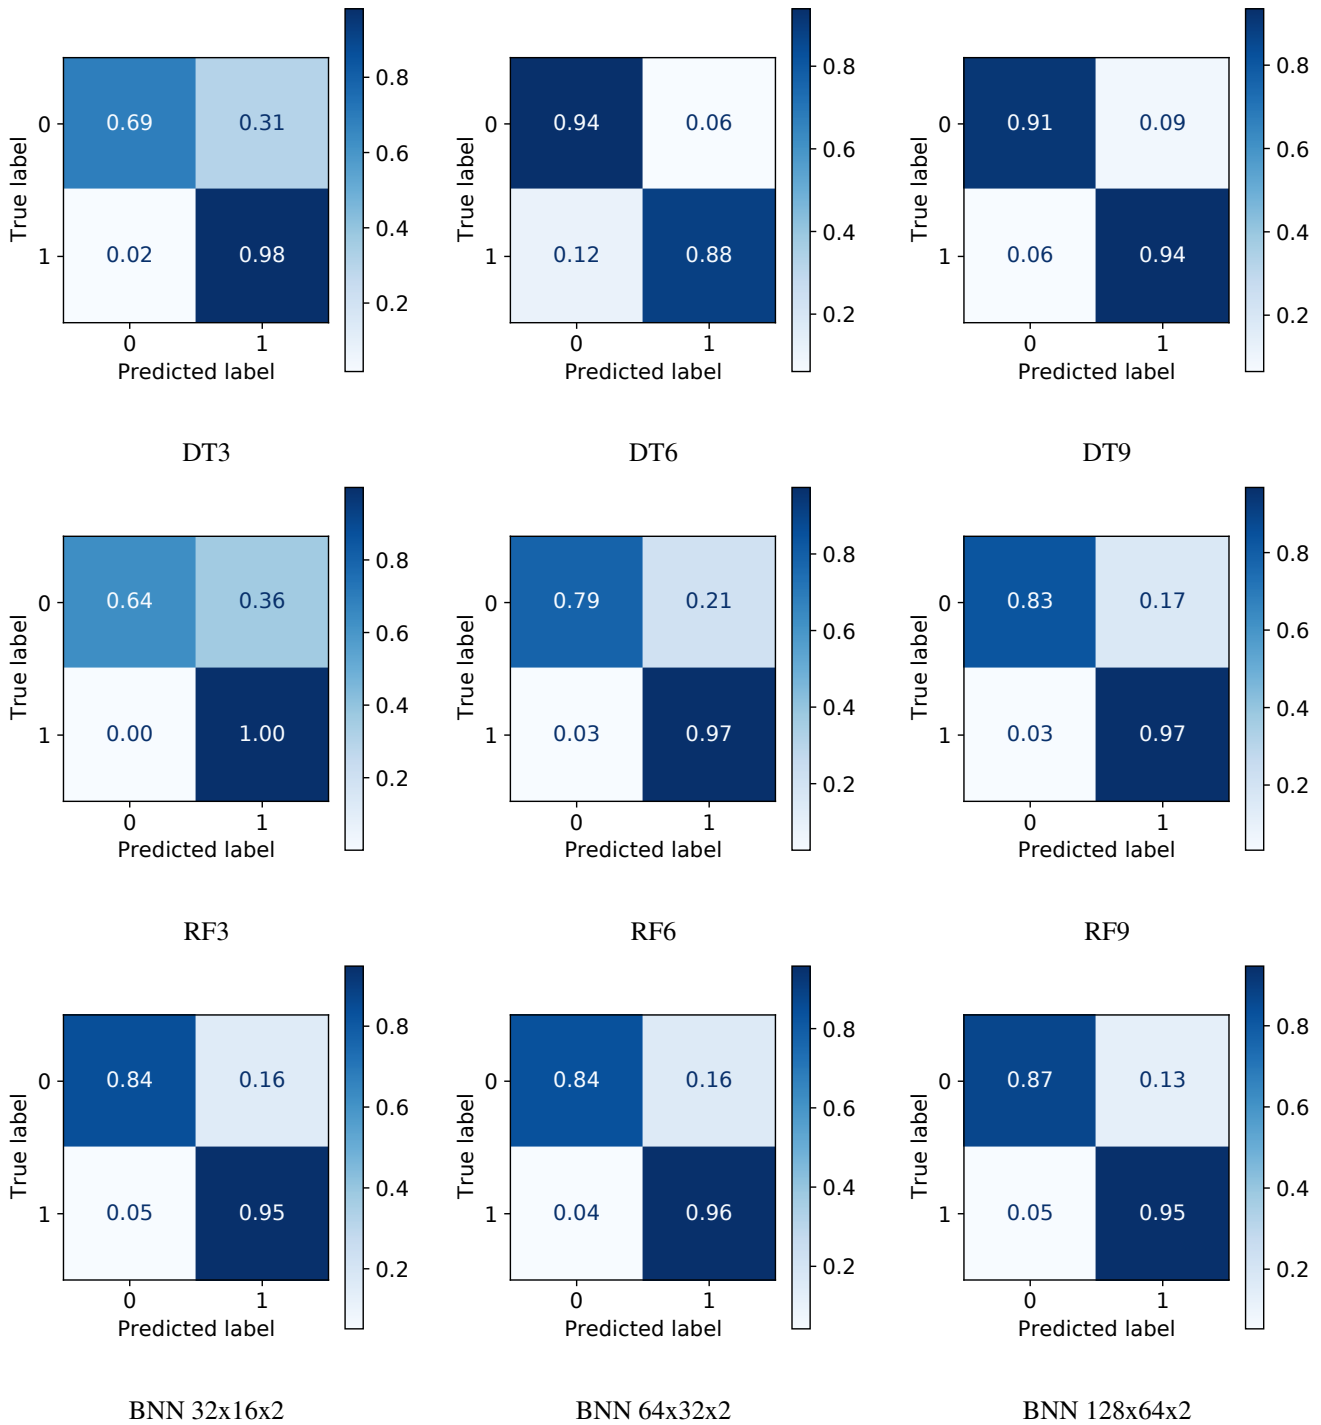
To keep the implementation as simple as possible, we do not perform any TCP connection tracking for TCP flows. To measure the flow features that we need for traffic analysis, in fact, in this simpler implementation it is enough to track the initial TCP handshake (e.g., to extract SYN-ACK RTTs). To measure flow duration, instead, we store the timestamp of the first packet of a flow (recognized by the absence of a flow entry in the flow hashtable) and check the timestamp of the


Figure 20: Confusion Matrices for the Security Anomaly Detection use case

last received flow's packet.

Flow entries are removed from the hashtable if no packets match them for a given amount of time. This is implemented as a lightweight task that can be performed lazily. For instance, when a new packet is received, if there is already an entry for the corresponding flow, but `current time -` `last packet timestamp > timeout value`, then the existing entry is discarded and the flow is considered as a new flow, and the received packet as the first packet of this flow. The timeout value should be configured depending on the deployment environment, taking into account the properties of the monitored traffic. For instance, in telecom operators
Figure 21: TCP Connection Tracking state machine, reported from [36]

A.3.2 Feature Extraction with connection tracking

The simpler implementation presented earlier is not safe in presence of misbehaving packets. For instance, an attacker may forge packets to impact the measured flow's features. This is possible, since the flow counters are only retrieved using the packet's 5-tuple, which in a general case may be e.g., forged. To avoid this class of issues, for TCP flows it is possible to perform TCP Connection Tracking. Connection tracking verifies that the flow's behavior is consistent with the TCP's state machine, and it includes fine granular per-packet checks, e.g., reading sequence and ack numbers.

We implement TCP connection tracking using the implementation presented in FlowBlaze [36], and the state machine is reported in Figure 21. Here, it should be noted that the state machine is in fact a sequential composition of two state machines. This is a by-product of using the FlowBlaze abstraction, which implements state machines in a sequence of stages that resemble a match-action pipeline similar to that of devices supporting the P4 language.

The two state machines are always executed in sequence, for each packet of an established connection. However, it is possible to identify different responsibilities of each of the two state machines. The first one tracks connection establishment, and computes the allowed sequence numbers (e.g., computing Rwin and Lwin). These values are *forwarded* to the second state machine that performs the actual checks, and which also implements the transitions to check the connection termination.

We implemented this connection tracking solution both in the NetFPGA and in the Netronome NIC. For the NetFPGA, we add two FlowBlaze stages in front of the N3IC design. These two stages are used to then to implement the state machine of Figure 21. For the Netronome, we implement the state machine of Figure 21 using micro-C, and extending the N3IC's Netronome firmware.

Elixir: A High-performance and Low-cost Approach to Managing Hardware/Software Hybrid Flow Tables Considering Flow Burstiness

Yanshu Wang[★], Dan Li[★], Yuanwei Lu[†], Jianping Wu[★], Hua Shao[★], Yutian Wang[★]

[★]*Tsinghua University,* [†]*Tencent*

Abstract

Hardware/software hybrid flow table is common in modern commodity network devices, such as NFV servers, smart NICs and SDN/OVS switches. The overall forwarding performance of the network device and the required CPU resources are considerably affected by the method of how to split the flow table between hardware and software. Previous works usually leverage the traffic skewness for flow table splitting, *e.g.* offloading top 10% largest flows to the hardware can save up to ∼90% CPU resources. However, the widely-existing *bursty flows* bring more challenges to flow table splitting. In particular, we need to identify the proper flows and proper timing to exchange the flows between hardware and software by considering flow burstiness, so as to maximize the overall performance with low overhead.

In this paper we present Elixir, a high-performance and low-cost approach to managing hardware/software hybrid flow tables on commodity devices. The core idea of Elixir includes three parts, namely, combining sampling-based and counter-based mechanisms for flow rate measurement, separating the replacement of large flows and bursty flows, as well as decoupling the flow rate identification window and the flow replacement window. We have implemented Elixir prototypes on both Mellanox ConnectX-5 NIC and Barefoot Wedge100BF-32X/65X P4 Switch, with a software library on top of DPDK. Our experiments based on real-world data traces demonstrate that, compared with the state-of-the-art solutions, Elixir can save up to ∼50% software CPU resources while keeping the tail forwarding latency ∼97.6% lower.

1   Introduction

With more and more packet header fields taken as the input for forwarding rules, the size of flow table in modern network devices grows rapidly [3, 4, 59, 64, 71]. Although hardware has fast forwarding speed, the hardware on-chip memory (typically containing <6M flows [13, 49, 50]) usually cannot serve all the concurrent flows (typically with an order of O(10M) [31]). On the contrary, the software has large memory

and limited forwarding capacity. As a result, many commodity network devices, such as NFV servers, smart NICs and SDN/OVS switches, take a hardware/software hybrid way to manage the large flow table [4, 15, 16, 61]. By using this kind of hybrid flow table, the typical packet forwarding process is as follows. Upon receiving traffic, the hardware extracts certain fields from the received packet's header. If an entry in the hardware flow table is hit, the action associated with the entry is executed on the packet; otherwise, the packet is forwarded to CPU to match the software flow table.

In this scenario, it is important to figure out how to split the flow table between hardware and software. The splitting method not only affects the forwarding performance, but also determines the CPU resources reserved for software forwarding, which is of particular importance for cloud environment. Previous works usually leverage the traffic skewness for flow splitting [5, 15, 18, 53, 55, 61, 73], *e.g.* offloading top 10% largest flows to the hardware can save up to ∼90% CPU resources. However, the wide existence of *bursty flows* [19, 25, 33, 48, 52] brings more challenges to be addressed to flow table splitting, for maximizing the overall forwarding performance with low overhead.

First, how to accurately measure all the flow rates with low overhead on commodity devices?

The dynamic flow replacement between hardware and software requires a timely and accurate identification of all the flow rates including bursty ones. As the hardware flows bypass the software, the measurement cannot be done solely by software. Commodity hardware devices, such as Mellanox NICs and P4 Switches, support both putting a hardware counter to every flow and sampling the hardware traffic to software. The cost of using hardware counters for flow rate measurement is very high (more discussion in Section 2). If sampling a portion of the hardware traffic to software for measurement, a too large sampling rate wastes many CPU resources while a too small sampling rate might miss bursty flows, which can result in packet loss. Given a certain sampling rate, we should also set a proper window size for accurate flow rate identification. Therefore, we need a method to

accurately measure all the flow rates with low overhead on commodity devices, so as to identify the appropriate set of flows for replacement.

Second, how to set the proper timing for flow replacement between hardware and software?

Due to traffic dynamics, some flow table entries in hardware and software should be exchanged over time. Conventional approaches make periodic replacement, *i.e.* if a software flow's rate becomes larger than a hardware flow's rate within a time window, the two flows are exchanged with each other. However, in practice we find it difficult to set the proper window size for periodic replacement. In order to timely offload software flows whose rates turn large, the window should be as small as possible. However, the small window will lead to frequent flow table replacement. In the high-speed packet forwarding scenario, too frequent flow table replacement will cause considerable performance degradation, in both hardware and software. On the other side, if we set a large replacement window to mitigate forwarding performance degradation, bursty flows with lower average rate than stable flows might be kept in software. To prevent packet loss of these bursty flows, we have to provision much more CPU resources for the peak rate, which is usually several orders of magnitude higher than the average rate. It is a considerable waste of CPU resources. Therefore, we have to solve this dilemma of setting the proper flow replacement window between hardware and software.

In this paper, we propose Elixir, a high-performance and low-cost approach to managing hardware/software hybrid flow tables on commodity devices, by taking flow burstiness into account. Elixir deals with the aforementioned challenges as follows.

First, Elixir combines both sampling-based and counter-based mechanisms for the rate measurement of large flows and bursty flows, respectively. For large flows, packets are sampled from hardware to software with a low sampling rate, so as to reduce the processing overhead on CPU. For bursty flows that are easy to be missed by low-rate sampling, hardware counters are put to each flow, since the number of concurrent bursty flows is not quite large (based on our observation from real traces). By this method, Elixir leverages the benefit of both hardware and software solutions to get the balance between measurement accuracy and measurement overhead.

Second, Elixir separates the replacement processes of large flows and bursty flows. For large flows, due to their stable rate changing pattern over time, Elixir periodically exchanges large flows between hardware and software. A relatively large replacement window is used to offload large flows with the highest average rates during this window, so as to avoid the throughput degradation caused by too frequent replacement. Meanwhile, for bursty flows, as they appear in the system at irregular basis, Elixir leverages an event-driven process to offload them to hardware, *i.e.* bursty flows are offloaded

immediately when they are detected. By observing that the size of software queue increases dramatically when a bursty flow comes, Elixir uses it as a signal to trigger the bursty flow offloading process. In this way, Elixir makes the tradeoff between burst-aware offloading and forwarding performance degradation caused by frequent replacement.

Third, Elixir decouples the flow rate identification window and the flow replacement window. Previous works [6, 21, 66] make no distinction between the two windows. In principle, the flow rate identification window is determined by traffic characteristics while the flow replacement window is determined by hardware/software system limitations. Consequently, using one size for the two windows may either sacrifice the flow rate identification accuracy, or lead to lagged flow replacement. Elixir explicitly decouples the two and independently decides the proper sizes for them. For large flows, the flow replacement window is set to the minimum replacement decision interval which brings affordable impact on the forwarding performance; while the flow rate identification window is set to the minimum window which can accurately identify flow rates, since the sampled traffic may cause inaccurate rankings of large flow rates. For bursty flows, the flow rate identification window is set to be small enough to catch the flow burstiness and they are offloaded immediately once detected. By the decoupling, Elixir achieves the tradeoff between timely flow replacement and accurate flow identification.

We have implemented Elixir prototypes on both Mellanox ConnectX-5 NIC and Barefoot Wedge100BF-32X/65X P4 Switch, with a software library on top of DPDK. We run experiments based on the real-world traces from cloud gateways of an Internet content provider. The results show that Elixir can save up to ∼50% software CPU resources while keeping the tail forwarding latency ∼97.63% lower compared with TFO [61] and ∼97.61% lower compared with LFP [15].

2 Motivation and Challenges

In this section, we first describe the findings from traffic measurement of typical cloud gateways, then we present the design challenges for a hardware/software hybrid flow table management solution.

2.1 Traffic Measurement of Cloud Gateways

We examine three cloud gateways of an Internet content provider. The gateways run on commodity servers using hardware/software hybrid flow tables. We collect traffic traces from all the three gateways. The data path of these gateways manipulates packet headers and forwards them with tunnels, *e.g.* GRE or VxLAN [17, 43]. For each gateway, we have collected the real-time packet-level traces of a work day. In what follows we describe our key findings from the traffic traces of the three gateways. Due to page limits, we only present the results for one gateway, since the traffic characteristics of the other two are quite similar.

(b) Distribution of the numbers of concurrent bursty flows.

Figure 2: The characteristics of bursty flows in the cloud gateway trace.

(a) Queue size and latency.

(b) Packet loss rate against different software-forwarding CPU cores.

Figure 3: The cost of forwarding the bursty flow and the stable flow by software.

Large flows constantly change over time: The rates of flows dynamically change over time. For the traces, we set the flow rate identification window to different sizes, *i.e.* from 1 second to 300 seconds. For each window size, we measure the top 10% flows with the largest flow rates in every time window (referred to as *large flows*), and count the number of changed large flows between neighboring windows within a 10-minute period. Then we divide this number by the total number of the flows to calculate the accumulated change rates of large flows. Fig. 1 shows the accumulated change rates of large flows within the 10-minute period. We find that large flows constantly change over time. It indicates that, in order to efficiently manage the hardware/software hybrid flow table and offload large flows to hardware, the flow table entries in hardware and software need to be periodically exchanged. Moreover, given a fixed time period, a smaller flow rate identification window leads to higher accumulated changes of large flows between neighboring windows.

Bursty flows are common: Previous works on flow table splitting primarily consider offloading *large flows*, with a focus on the average flow rates during a time period. They pay little attention to *bursty flows*, of which the flow rates surge to a high value quickly and last for a short time period before dropping to a low rate. Bursty flows are very common in both backbone and datacenter networks [19, 25, 33, 48, 48, 52], which may come from bursty applications (such as video application), TCP incast, or batching operation of network stacks [48].

Conceptually, a bursty flow can be or not be a large flow; besides, a large flow can be either a bursty large flow during some periods while a stable large flow during other periods. In order to study the impact of bursty flows, we measure the rate changing pattern for each individual flow in the cloud gateway trace.

The results show that bursty flows are also quite common in the trace. We use the ratio of a flow's peak rate (in a second) over its average rate, named *burst ratio*, to describe the level of flow burstiness. We depict the CDF of burst ratio in Fig. 2(a). As shown in the figure, ~80% of the flows have a >20 burst ratio, with the maximum ratio as high as 80. By examining the data, we find that the peak rate duration of most bursty flows is very short, *e.g.* several seconds. Moreover, we make
statistics about the distribution of the numbers of concurrent bursty flows (using bursty flows with a >10 burst ratio in the case), shown in Fig. 2(b). We find that, although bursty flows are common, their bursty times are usually not overlapped. In other words, the number of concurrent bursty flows is limited, *e.g.* with the largest number as 36 in our trace.

Bursty flows require more software forwarding resources: We further carry on experiments to quantitatively compare the cost of forwarding bursty flows and stable flows by software. We use three servers, one as the sender, one as the receiver and the third as the software forwarder. We purposely generate a stable flow and a bursty flow at the sender. Notably, the average rate of the stable flow is 5 times higher than that of the bursty flow. Each flow is only forwarded by the software.

We first use one CPU core at the software forwarder. We separately run the two flows, and record the end-to-end latency as well as the queue size at the software forwarder. The results are shown in Fig. 3(a). It indicates that, for the stable flow and the stable periods of the bursty flow, the queue size is small and the end-to-end latency is low; but at the peak rate period of the bursty flow, the queue size and the end-to-end latency sharply increase, by a maximum of ~30 and ~28 times respectively.

Then we use different numbers of CPU cores at the software forwarder to forward the two flows and measure the packet loss rates. As demonstrated by Fig. 3(b), although the average rate of the bursty flow is only one fifth of the stable flow, the software forwarding resources required by the bursty flow are 4 times of the stable flow to avoid packet loss. Specif-

ically, to prevent packet loss from occurrence, at least 4 CPU cores are required at the software forwarder for the bursty flow, while only 1 CPU core is needed for the stable flow. In conclusion, since the CPU resources should be reserved for the peak rate of a flow instead of the average rate to prevent packet loss, in practice bursty flows occupy remarkably more software forwarding resources than stable flows.

2.2 Design Challenges

Previous works [15, 55, 61, 73] on managing hardware/software hybrid flow tables usually leverage the traffic skewness for flow table splitting, *i.e.* offloading a small portion of the largest flows to the hardware can save most of the CPU resources. However, by considering flow burstiness, more challenges have to be addressed, so as to maximize the overall performance with low overhead.

Challenge 1: how to accurately measure all the flow rates with low overhead on commodity devices?

An accurate and low-cost approach to measuring all the flow rates is critical in hybrid flow table management on commodity devices. Note that hardware can see all the flows but software can only see the software-forwarded flows, hence the flow rate measurement cannot be done without the support of hardware. Knowledgeable readers may consider building a sketch data structure [12, 23, 39, 41, 68–70, 72, 74] in hardware to measure all the flow rates. However, commodity hardware does not support this kind of functionality yet. Besides, a sketch for so many flows consumes too many resources in hardware, which can be saved for storing more forwarding rules.

Modern commodity hardware devices, such as Mellanox NICs and P4 Switches, support both putting a hardware counter to every flow and sampling the hardware traffic to software (Mellanox plans to support the sampling functionality in the new release). Hence, one candidate solution is to place a hardware counter for each flow and use the counters to accurately measure each flow's rate. However, there are two problems for this method. First, setting a counter for each flow occupies additional hardware resources. Based on our measurement, hardware counters result in ∼ 20% less space for hardware (NIC and switch) forwarding rules, which will result in much more traffic forwarded to software and much more CPU resources consumed consequently. Second, the speed for software to read the counters from commodity hardware devices is slow, *e.g.* the speed is about 20k rules per second for Mellanox ConnectX-5 NIC. It means that several seconds are required for the software to read all the hardware counters, which is too slow for timely flow replacement.

The final optional solution is to sample a portion of hardware traffic to software and use the software to measure all the flow rates. However, as the peak rate duration of bursty flows is quite short, a high sampling rate is required in order not to miss them; otherwise, bursty flows might not be correctly identified to offload from software to hardware, or might be

Figure 4: Miss probability of bursty flows against different sampling rates.
(a) Identification probability of bursty flows.

(b) Replacement frequency of large flows.

Figure 5: Identification probability of bursty flows and replacement frequency of large flows against different time window sizes.

replaced from hardware to software by mistake. As shown in Fig. 4, in the cloud gateway trace, a 20% sampling rate will lead to a probability of 76% to miss bursty flows. However, if we set a high sampling rate, much more CPU resources will be occupied. Hence, it is a dilemma how to set the proper sampling rate if we use a sampling-based measurement approach.

As a result, we have to design an accurate and low-cost flow measurement method, by overcoming the problems above.

Challenge 2: How to set the proper timing for flow replacement between hardware and software?

Conventional approaches make periodic flow replacement between hardware and software, *i.e.* if a software flow's rate becomes larger than that of a hardware flow within a periodic time window, the two flows are exchanged with each other. Following this approach, as discussed above, if we set a large time window to replace flows between hardware and software, bursty flows might have lower average rate than stable flows during this window and thus be kept in software. It will result in more CPU resources reserved for software forwarding. Based on the cloud gateway trace, we make further analysis to measure the probability for bursty flows to rank higher than stable flows, *i.e.* bursty flows being identified as large flows to offload by previous solutions, against different identification window sizes. As shown in Fig. 5(a), for bursty flows to rank higher than stable flows with >60% probability, the identification window should be as small as <2 seconds.

On the other side, if we set a small time window for flow replacement, it usually means much more flows to exchange between hardware and software during a fixed time period
(a) Hardware throughput against different replacement window sizes and numbers of initialized rules.

(b) Software throughput against different replacement window sizes.

Figure 6: Forwarding speed will be degraded by frequent flow replacement between hardware and software.

(refer to Fig. 1). In other words, a small flow replacement window results in high replacement frequency. It is validated by Fig. 5(b), which shows the replacement frequency against different replacement window sizes based on the cloud gateway trace, *e.g.* a 2-second replacement window results in a replacement frequency of 3.25k/s.

Unfortunately, high replacement frequency causes forwarding speed degradation, in both hardware and software. For hardware, it cannot keep forwarding traffic at a high rate with too frequent rule replacement, due to the lock mechanism used. We measure the forwarding speed under different replacement frequencies using a commodity Mellanox ConnectX-5 NIC. As shown in Fig. 6(a), with 50k initial hardware flows updated at a replacement frequency of 3.25k/s (2-second time window), the NIC throughput drops by 50%. For Barefoot P4 Switches, today the vendors limit the maximum replacement frequency to 2k/s, which can merely avoid obvious performance degradation during replacement. For software, frequent replacement leads to cache contention and results in many cache misses, which can also degrade the forwarding throughput. Specifically, in our trace, the software throughput drops by 16% at a replacement frequency of 3.25k/s, as shown in Fig. 6(b).

Therefore, if a conventional periodic replacement method is used, we have to resolve the dilemma of how to set the proper size of the time window for high-performance hybrid flow table management.

3   Design

In this section, we elaborate the design of Elixir. We first describe the design overview, and then separately present the design details of large flow replacement and bursty flow replacement.

3.1   Design Overview

Elixir takes the following key ideas to address the challenges discussed in Section 2.

First, Elixir uses different methods for measuring the rates of bursty flows and large flows. As large flows usually comprise of many packets, a small portion of sampled traffic can give relatively accurate information about flow characteristics.

Motivated by that, Elixir samples hardware traffic to software with a low sampling rate, so as for large flow identification. Observing that the number of concurrent bursty flows is small (refer to Fig. 2(b)), Elixir associates each bursty flow with a hardware counter and the software polls the counters for flow rate measurement.

As different measurement techniques are used for large flows and bursty flows, Elixir separates the hardware flow table into two disjoint areas, *i.e.* a large flow area and a bursty flow area. Large flows and bursty flows are inserted into corresponding areas accordingly. It is worth noting that, if a flow is both a large flow and a bursty flow (as discussed in Section 2), we insert the flow's forwarding rule to the corresponding hardware area where the replacement mechanism is firstly triggered for the flow. In principle, no matter in which hardware area is the forwarding rule stored, the flow will be forwarded by hardware and will not cause packet loss in software. Hence, when the flow turns from a bursty large flow to a stable large flow or vice versa, it is unnecessary to move the flow to other hardware area.

By this method, Elixir leverages the benefits of both hardware and software solutions to get the balance between measurement accuracy and measurement overhead.

Second, Elixir separates the replacement of large flows and bursty flows, due to their distinct characteristics. As shown in Fig. 1, large flows constantly change over time. If not adjusted periodically, throughput of software traffic may gradually increase, leading to higher CPU usage. It indicates that we need a periodic process to exchange large flows between hardware and software, and the replacement window can be set relatively larger, so as to bring affordable impact on the overall forwarding performance.

In contrast, bursty flows appear in the system at irregular basis, and cause a sharp increase of the queue size and forwarding latency. If not offloading software-forwarded bursty flows quickly, it may result in severe packet loss. As a result, we need to detect the existence of bursty flows quickly and offload them as soon as possible, which is an event-driven procedure.

Overall, Elixir handles large flows and bursty flows separately with distinct methods, *i.e.* large flows are offloaded periodically while bursty flows are offloaded immediately once detected. In this way, Elixir makes the tradeoff between burst-aware offloading and forwarding performance degradation caused by frequent replacement.

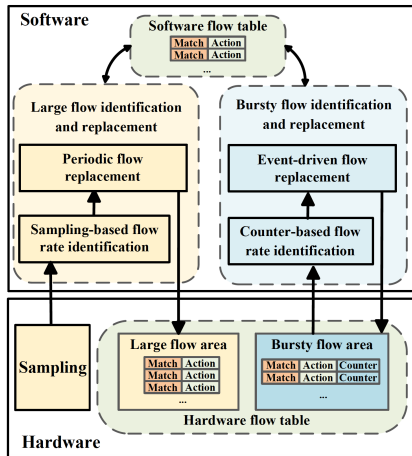
Third, Elixir decouples the flow rate identification window and the flow replacement window. Flow rate identification window (referred to as *identification window* for short in the rest of this paper) is the time window to measure the flow throughput, *i.e.* flows that generate the most traffic within the window are identified as the large flows. As a result, the size of the identification window should be determined by traffic pattern. Differently, flow replacement window (referred to as *replacement window* for short in the rest of this paper) is


Figure 7: Architecture overview of Elixir.

Figure 8: Identification accuracy against different sampling rates and identification window sizes.

Figure 9: Percentage of software traffic increase against different identification window sizes and replacement window sizes.

the time window between two adjacent hardware/software flow replacement decisions, which has close relationship with hardware/software system characteristics, *i.e.* too frequent flow replacement causes the performance degradation of both hardware and software. Consequently, using one size for the two windows may either sacrifice the flow rate identification accuracy or lead to lagged flow replacement.

Based on the observation, Elixir explicitly decouples the identification window and the replacement window. Specifically, for large flows, the replacement window is set to the minimum replacement decision interval which brings affordable impact on the forwarding performance; while the identification window is set to the minimum window which can accurately identify flow rates, since the sampled traffic may cause inaccurate rankings of large flow rates. For bursty flows, the identification window is set to be small enough to catch the flow burstiness, and they are offloaded immediately once detected.

By this decoupling, Elixir achieves the tradeoff between timely flow replacement and accurate flow identification.

Based on the key ideas above, the architecture overview of Elixir is shown in Figure 7. Two different policies are separately run for large flows and bursty flows. For large flows, periodic replacement policy is used, with sampling-based rate identification and a relatively large replacement window; for bursty flows, event-driven replacement policy is adopted, with counter-based rate identification and the software queue size as the replacement signal.

3.2 Periodic Large Flow Replacement

As aforementioned, Elixir leverages a periodic procedure to exchange large flows between hardware and software, and the rates of large flows are identified using sampled traffic.

Setting the sampling rate and the identification window size: When sampling the hardware traffic to software, in order to reduce the computation and storage overhead in software, a low sampling rate is required. To further reduce
the hardware/software communication cost, the payload of every packet is cut and only the packet header is delivered from hardware to software. Since we use a low sampling rate, a flow's ranking in the sampled traffic may be different from its ranking in the actual traffic, which leads to inaccurate selection of flows to replace. Generally, a higher sampling rate or a larger identification window not only results in more accurate flow rate rankings as it sees more packets, but also means that more CPU and memory resources are required for flow rate identification in software. In a practical system, the sampling rate and the identification window size should be set by taking multiple factors into account, including CPU overhead, memory overhead and identification accuracy.

For the cloud gateway trace, Fig. 8 shows the rate identification accuracy [1] against different sampling rates and identification window sizes. Based on the results, we set the sampling rate to 20% and the identification window size to 30 seconds, which can achieve an identification accuracy of ~90%.

Setting the replacement window size: As aforementioned, Elixir decouples the identification window and the replacement window. When setting the replacement window size for large flows, if using a large window, some software flows which turn large cannot be timely offloaded, and the software-forwarded traffic may increase during the window, which causes more CPU resource consumption. If setting a small window, as shown in Fig. 6(a) and Fig. 6(b), the high replacement frequency may cause considerable forwarding performance degradation in both hardware and software.

---

[1] The rate identification accuracy is defined as the ratio of the number of top 10% largest flows that are correctly identified by our method over the total number of top 10% largest flows.

Figure 10: Data structures used in large flow identification and replacement algorithm.

Therefore, when setting the replacement window size, there should be a tradeoff between timely offloading and forwarding performance degradation caused by frequent replacement.

Ideally, if we can replace large flows as quickly as possible, *i.e.* immediately offloading a software flow when its rate becomes larger than a hardware flow, we can get *the smallest software traffic*. In practice, a large replacement window will cause lagged offloading and thus the actual software traffic will be larger than the smallest one. We measure the *percentage of traffic increase* in software against different identification window sizes and replacement window sizes, as shown in Fig. 9. It is worth noting that, under different identification window sizes, the same replacement window may also lead to different software traffic. For the identification window size of 30 seconds we choose for the cloud gateway trace, the additional software traffic is negligible when the replacement window is smaller than 10 seconds.

From Fig. 6, we find that when the replacement window is smaller than 10 seconds, the hardware and software forwarding speeds will degrade significantly. To make the tradeoff between the two factors, we can set the replacement window size to 10 seconds for the cloud gateway trace.

Identification and replacement algorithm for large flows: Based on the window setting rules discussed above, in a practical system the replacement window can be either smaller or larger than the identification window. In most cases when the replacement window is smaller than the identification window (*e.g.* for the cloud gateway trace), the identification window is actually a sliding window with the replacement window as the sliding step size. When the replacement window is larger than the identification window, which should be rare cases, we increase the identification window to the replacement window, since more information about the traffic results in more accurate flow rate rankings.

As shown in Fig. 10, we employ sketch and min-heap data structures to estimate the sizes of flows[2] received in an identification window. Assuming L is the identification window size and T is the replacement window size, there is $N = \lceil \frac{L}{T} \rceil$. Elixir uses N two-dimensional arrays to record a flow's re-

---

[2]The flow rate is obtained via dividing the flow size by the identification window size.

ceived packets in N sub-windows respectively, with the sub-window size set to the replacement window size T. Each two-dimensional array consists of d groups of buckets. A sampled packet is hashed into one of the buckets in different groups of the same two-dimensional array in the sketch structure, and each bucket contains a counter which will be increased by one upon packet arrival. The flow size can be calculated from the sums of all the corresponding counters in each sub-window. The minimum value of the counter sums associated with a flow is considered as the flow size. All the flows are then fed into a min-heap data structure for sorting, which yields the largest flows. Of course, if $N = 1$, which means that the replacement window is larger than or equal to the identification window, there is only one array in the identification window.

Algorithm 1 The identification and replacement algorithm for large flows.

Input: The identification window L, the replacement window T, the flow f of the incoming packet, a set of hash functions $h_j(j = 1, 2, 3...d)$, an array A[.][.][.], the current replacement window t initialized as 0, and a min-heap *min_heap*.

1: $N \leftarrow \lceil \frac{L}{T} \rceil$
2: **for** j=1 to d **do**
3:     A[j][$h_j(f)$][t]++
4: **end for**
5: flow_size $\leftarrow 0$
6: **for** j=1 to d **do**
7:     $C = \sum_{t=1,2,...,N}$ A[j][$h_j(f)$][t]
8:     **if** C < flow_size **then**
9:         flow_size = C
10:     **end if**
11: **end for**
12: **if** $f \in$ min_heap **then**
13:     min_heap[f] $\leftarrow$ flow_size
14: **else if** min_heap has empty buckets **then**
15:     min_heap.insert(f, flow_size)
16: **else if** flow_size > min_heap$_{min}$ **then**
17:     min_heap.delete_root()
18:     min_heap.insert(f, flow_size)
19: **end if**
20: **if** (time.now() $-$ pre_time_r) $\geq T$ **then**
21:     pre_time $\leftarrow$ time.now()
22:     current_flows $\leftarrow$ min_heap.all_flows
23:     replace_rules(previous_flows, current_flows)
24:     previous_flows $\leftarrow$ current_flows
25:     t $\leftarrow$ (t + 1) mod N
26:     min_heap.reset()
27:     A[.][.][t] $\leftarrow 0$
28: **end if**

The flow replacement operation is enforced at every T time. When flow replacement is finished, the identification window moves over T time and forgets the counters for the oldest replacement window (if the identification window is smaller than or equal to the replacement window, all the counters are reset). As there are several groups of counters, a naive

design would require a touch at each counter in each group when resetting the counters, which will heavily decrease the processing performance. Instead, Elixir arranges the counters of the same replacement window into an array. Thus each time the identification window moves, only the array which records the oldest counters needs to be reset, which is a piece of continuous memory and can be processed fast. When the identification window updates, the heap which keeps the rankings of the large flows is rebuilt using the latest packet counters. We use a bloom filter [7] to record the offloaded hardware flows, which are compared with identified large software flows to determine which software flows to offload to hardware as well as which hardware flows to upload to software.

Algorithm 1 presents the pseudo code of the identification and replacement algorithm for large flows. Lines 1 calculates the number of the two-dimensional arrays, lines 2–4 describe the update process of the sketch data structure, lines 5–19 show the update process of the min-heap data structure, lines 20–24 illustrate the flow replacement process, and lines 25–28 demonstrate the update process of the identification window.

3.3 Event-Driven Bursty Flow Replacement

Elixir leverages an event-driven process to detect and offload bursty flows, *i.e.* when the software queue size exceeds a pre-defined threshold (K), one or more bursty flows in the software need to be offloaded to the hardware. It indicates that, if there is a bursty flow in the software but the queue size is smaller than the threshold, Elixir does not trigger event-driven replacement (instead, only periodic large flow replacement is carried on), so as to reduce the potential performance degradation caused by the frequent replacement. It is also worth noting that, Elixir can never promise there is no packet loss in the software forwarding system; instead, Elixir can only try its best to offload bursty flows that may cause packet loss. For an extreme example, if all the flows are bursty at the same time, it is impossible to offload all the flows immediately to avoid packet loss.

When triggering the bursty flow offloading process, hardware counters of the flows which are maintained in the hardware bursty area are polled to software. By a small identification window to compare the hardware and software flows, the corresponding flows are determined for replacement.

Setting the threshold of software queue size: Many modern practical software forwarding systems use high performance packet IO frameworks like DPDK [24] for packet processing. In these frameworks, the hardware and software communicate via a ring buffer and the hardware directly places packets into the ring buffer. When the software forwarding speed cannot catch up with the traffic receiving rate during the traffic burst period, packets will be lost at the NIC ring buffer and the queue size will become large. Apparently, a sudden increase of the ring buffer queue size is a clear signal of the existence of bursty flows.

Algorithm 2 The identification and replacement algorithm for bursty flows.

Input: The queue size threshold K.
1: **if** get_queue_size() $\geq K$ **then**
2:     $f_{bursty} \leftarrow$ get_hardware_bursty_flows()
3:     $c_{bursty} \leftarrow$ poll_flow_counters(f_{bursty})
4:     $f_{replaced} \leftarrow$ get_the_smallest_flow(f_{bursty}, c_{bursty})
5:     $f_{offloaded} \leftarrow$ get_offloaded_flow()
6:     **if** ($f_{offloaded}$.size > $f_{replaced}$.size) **then**
7:         replace_hardware_flow($f_{replaced}, f_{offloaded}$)
8:     **end if**
9: **end if**

One problem here is how to set the threshold K for triggering bursty flow offloading. We borrow the idea used in setting the headroom size in the PFC mechanism [1]. In PFC, the headroom should be large enough to store the packets received by a switch between the time when the PFC pause message is sent and the time when the PFC pause message takes effect. Similarly, when setting the threshold K in Elixir, a headroom should be reserved to store the packets received by the NIC between the time when bursty flow offloading is triggered and the time when the flows responsible for the burst are successfully offloaded. Following this principle, the threshold K is set to $K =$ queue_capacity $-(t_{identification} + t_{offloading}) \times$ NIC_speed, where $t_{identification}$ is the time required for identifying the bursty flows and $t_{offloading}$ is the time taken for completing the offloading process. With this queue-based detection mechanism, Elixir can detect bursty flows in a fast way while avoiding packet loss during offloading.

Setting the identification window size: When the queue size indicates the occurrence of bursty traffic, Elixir should identify the exact flow that causes the bursty traffic and replace it with a hardware flow that is no longer bursting. To achieve the purpose, Elixir not only associates each offloaded bursty flow with a hardware counter in the bursty flow area of the hardware as aforementioned, but also uses a counter to measure the accurate rate of each software-forwarded flow. In order to catch the flow burstiness, the identification windows of both software counters and hardware counters are small, *i.e.* they are reset every small time window. For the cloud gateway trace, we set the identification window for the counters to 1 second. As shown in Fig. 5(a), an identification window of 1 second can make bursty flows rank higher than stable flows with >60% probability.

It also indicates that, the additional cost of software counters is not high, since the total traffic volume forwarded by software is much smaller than that forwarded by hardware, and the software only needs to maintain a identification window of 1 second.

Identification and replacement algorithm for bursty flows: When traffic burst is detected in software, Elixir immediately polls the hardware counters to software. The process

is fast since the number of hardware counters in the bursty flow area is small. All the hardware counters and the software counters are sorted together to find the flows with the highest flow rates. A software flow will be offloaded if its rate is larger than that of a flow in the bursty flow area of hardware.

Algorithm 2 presents the pseudo code of identification and replacement algorithm for bursty flows in Elixir. Line 1 shows the queue-based bursty detection, lines 2–3 describe the process of polling the counters from the bursty flow area in hardware, and lines 4–9 demonstrate the replacement process of bursty flows.

It is worth noting that, the replacement processes of large flows and bursty flows are independent. Although their hardware flow tables are separated, the software flow table is shared between the two processes. Therefore, it may happen that both processes decide to offload a *bursty and large* software flow. In this case, the faster process will complete the offloading process, while the slower process will fail in flow offloading. It will not impact the correctness of flow replacement, and it does not matter which process finishes the flow offloading.

4   Implementation

We have implemented two Elixir prototypes. One is implemented on a server with an offloading-capable Mellanox ConnectX-5 NIC, and the other is implemented on a server connecting a Barefoot Wedge100BF-32X/65X P4 Switch. The switch supports both traffic sampling and hardware counters. The NIC only supports hardware counters currently, although Mellanox company plans to support the sampling functionality in the new release based on our knowledge. In our implementation, we direct the NIC traffic to a switch for sampling.

On the software side, we develop an Elixir library on top of DPDK (version 20.08), with ~3k lines of C codes. The library has three primary components, namely, software queue monitor, traffic analyzer and flow table manager. For offloading the flow tables to the NIC, Elixir manages the NIC hardware flow table with DPDK *rte_flow* API to support hairpin function, *i.e.* a flow bypasses the software when a hardware flow table entry is matched. For switch offloading, all the switch functions are implemented by programming the switch pipeline with PD API (Program Dependent API) [60].

Software queue monitor: Elixir leverages the software queue size as an indicator to offload software bursty flows. The queue size of the ring buffer can be calculated by polling several NIC pointers. We use the software consumer index pointer (rq_ci) and the hardware producer index pointer (rq_pi) to calculate the queue size as queue_capacity − (rq_ci − rq_pi). To achieve real-time bursty flow detection, Elixir reads the pointers upon each packet's arrival. For this reason, we implement the NIC pointer reading logic inside the DPDK packet receiving logic. Once a bursty flow is detected, the signal is passed to the flow table manager via a lockless queue.

Flow table manager: The flow table manager is responsible for managing the flow table entries in the hardware, *i.e.* offloading the flows selected by the traffic analyzer to hardware. For the NIC prototype, we leverage the *rte_flow_create* and *rte_flow_destroy* of the DPDK *rte_flow* API to insert and replace flow table entries in the NIC. For the switch prototype, we implement an RPC service in switch ONL (Open Network Linux) system, which modifies flow table entries via PD API when receiving offloading instructions from the flow table manager.

Traffic analyzer: Elixir implements the traffic analyzer component to identify the proper flows to offload. As aforementioned, the traffic analyzer identifies large flows through the sketch and min-heap data structures. In our implementation, it takes ~10ms to rebuild the heap after each replacement operation. For the NIC prototype, we leverage DPDK *rte_flow_query* to read the hardware flow counters from the NIC. For the switch prototype, the RPC service queries the flow counters and reports the results to the traffic analyzer.

5   Evaluation

In this section, we evaluate Elixir based on the prototypes we have developed. We first carry on a series of micro-benchmark experiments and then demonstrate the overall performance of Elixir.

5.1   Experimental Setup

Testbed: We build a testbed of 3 servers, namely, a packet sender, a packet receiver and a forwarder. The forwarder uses either the Elixir-NIC prototype (called the *Elixir-NIC forwarder*) or the Elixir-switch prototype (called the *Elixir-switch forwarder*), as described in Section 4. Each of the three servers is equipped with two 14-core Intel CPUs, 128GB RAM and 100GbE NICs. The OS of each server is ubuntu 16.04.5 LTS. For the *Elixir-NIC forwarder*, the NIC is Mellanox ConnectX-5 NIC with the firmware of 16.28.1002. For the *Elixir-switch forwarder*, the switch is Barefoot Wedge100BF-32X/65X P4 Switch, with one 4-core Intel CPU and 8GB RAM. We employ *dpdk_pkg_gen* version 20.08.0 together with DPDK version 20.05 to generate, forward and receive packets.

Comparison: We compare Elixir with three other solutions, namely, *Traffic-aware Flow Offloading (TFO)* [61], *Large Flow Predictor (LFP)* [15] and *Pure Software Forwarding (PSF)*. TFO and LFP represent the state-of-the-art hybrid flow table management solutions which only periodically replace large flows (without particular attention to bursty flows). TFO employs a sliding window to identify and replace large flows. LFP uses a learning method to predict and replace large flows. To keep consistency with the original papers [15, 61], we implement TFO in the Elixir-switch forwarder, while implement LFP in both the Elixir-switch

forwarder and the Elixir-NIC forwarder. PSF represents a baseline solution which forwards all the traffic by software, so it is only implemented in software.

Trace: We use the packet-level trace collected from the cloud gateway throughout this paper. The traffic shows a highly skewed pattern, namely, the top 10% largest flows comprise 91% of the total traffic. Besides, the packet sizes vary from 64 bytes to 1500 bytes. We use 10 minutes of the traffic trace for our experiments. When replaying the traffic trace, we control the average sending rate of the trace by *dpdk_pkt_gen*, so as to match different testing scenarios.

Elixir parameters: In the performance evaluation, we set the identification window of large flows to 30 seconds, the identification window of bursty flows to 1 second, the replacement window of large flows to 10 seconds, and the sampling rate to 20%. For Elixir, the large flow area in the hardware is set to contain at most 50k flows, while the bursty flow area in the hardware is set to contain at most 100 flows. For fair comparisons, in TFO and LFP, the hardware flow table is set to support 50.1k flows. The queue capacity of DPDK ring buffer is set to 64k packets. The queue threshold K is set to 28k packets for the Elixir-switch forwarder and 51k packets for the Elixir-NIC forwarder, according to the analysis in Section 3.3. For TFO, we use the default parameters in [61]. For LFP, we employ the J48 implementation [3] as the learning method and the first packet of each flow to predict the large flows, because this setting can achieve the best performance for LFP.

5.2 Micro-benchmarks

In the micro-benchmark experiments, we demonstrate that Elixir can identify the bursty flows timely and replace the identified bursty flows in a fast way. In addition, we show the advantage of Elixir over previous burst-oblivious replacement algorithms (TFO and LFP) with regard to bursty flow replacement.

Queue-based bursty flow detection: We purposely generate flows with the same average rate (∼5 Mpps) but different peak rates. When a flow sent from the sender begins to burst, we inject a special signal packet into the flow. The burst detection time is just the time interval between the time when the forwarder receives the signal packet and the time when the software queue size exceeds the threshold.

As shown in Fig. 11, the average detection time of bursty flows for Elixir-switch forwarder is 0.5∼6.0ms, while that for Elixir-NIC forwarder is 1.1∼11.0ms. The detection time is generally much lower than the peak rate duration of bursty flows, *i.e.* one or several seconds. The fast detection of the bursty flows gives us enough time to select and replace the bursty flows.

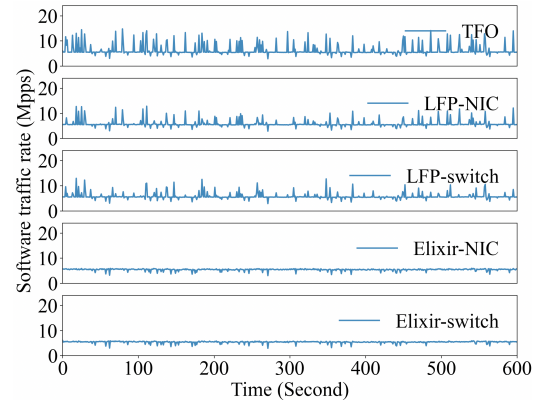
We also find out that the detection time of Elixir-switch forwarder is larger than that of Elixir-NIC forwarder, since it
Figure 11: Detection time of bursty flows against different peak rates.


Figure 12: Software traffic rate of bursty flow replacement.

takes more time for a bursty flow to exceed the larger queue threshold in the Elixir-switch forwarder. Besides, the detection time decreases as the flow peak rate increases. This is because it takes less time for the software queue size to exceed the threshold when the flow rate is larger.

Bursty flow identification and replacement: Elixir identifies the flow that is responsible for the bursty traffic and exchange it with a hardware flow which is no longer bursting. In this experiment, we verify that the bursty flow identification and replacement algorithm can accurately select the flow responsible for the bursty traffic and replace it timely. We purposely generate 30-minute traffic, with 1000 bursty flows bursting at different times. The average rate of the traffic is ∼5 Mpps. The peak rates of the bursty flows follow a uniform distribution from 6 Mpps to 50 Mpps. The experimental results show that 984 out of the 1000 bursty flows can be successfully identified. Of the 16 bursty flows that are not identified, 13 flows have been offloaded to the hardware and do not cause the queue size to increase, and 3 flows are not identified due to the measurement errors.

We also measure the time between the detection of the bursty traffic and the replacement of the bursty flow. The results show that the Elixir-NIC forwarder requires ∼0.0666 ms and the Elixir-switch forwarder needs ∼0.184 ms to replace the bursty flow. Hence, Elixir can provide timely bursty flow replacement.

Software-forwarded traffic: To intuitively demonstrate the effectiveness of Elixir in offloading bursty traffic, we measure the rate of software-forwarded traffic under Elixir-

---

[3]The Java implementation of the C4.5 algorithm [56].

Table 1: Latency, queue size and packet loss rate of different flow table management solutions.

| Methods | Case 1: without packet loss | | | | Case 2: fixed sending rate | | | | Loss rate |
| | Latency (μs) | | Queue size (Packet) | | Latency (μs) | | Queue size (Packet) | | |
	Ave	Tail	Ave	Tail	Ave	Tail	Ave	Tail	
Elixir-NIC	63.6	102.5	663.1	1121.6	63.6	102.5	663.1	1121.6	0%
Elixir-switch	78.0	137.5	863.1	1620.1	78.0	137.5	863.1	1620.1	0%
TFO	70.6	3970.5	726.2	53283.1	1396.3	5055.9	18610.8	64231.8	25.6%
LFP-NIC	46.2	3948.1	613.8	52865.9	1338.5	5003.8	17752.3	64173.2	22.9%
LFP-switch	69.8	3966.2	653.3	53197.6	1361.2	5032.1	18113.4	64214.5	24.1%
PSF	88.1	4392.6	1041.8	59488.7	4857.5	5071.1	64220.4	64285.2	81.3%

NIC forwarder, Elixir-switch forwarder, TFO forwarder, LFP-NIC forwarder and LFP-switch forwarder respectively. As shown in Fig. 12, Elixir can successfully keep the software-forwarded traffic at a stable and low rate, while there are many software traffic bursts in other methods.

5.3 Overall Performance

We evaluate the overall performance of Elixir by comparing it with TFO, LFP and PSF on the cloud gateway trace.

CPU consumption with fixed forwarding capability: To evaluate the resource consumption of Elixir, we set a fixed average sending rate (56 Mpps) and measure the packet loss rate of these solutions in software against different numbers of CPU cores consumed. The least number of CPU cores which can forward the traffic without packet loss is the minimum required CPU resources of each solution. Note that in Elixir, TFO and LFP, CPU cores are required not only for software forwarding, but also for flow rate measurement and sorting. For fair comparisons, we count all the required CPU cores. Of course in PSF, all the CPU cores are used for forwarding only.

As shown in Fig. 13, in our experiment Elixir needs only 2 cores to forward the traffic without packet loss. In contrast, TFO and LFP need 4 forwarding cores to prevent packet loss, while PSF needs 11 cores. It indicates that, for forwarding the same traffic without packet loss, Elixir can save 81.8% CPU resources compared with PSF while saving 50.0% CPU resources compared with the state-of-the-art solutions. Although in our experiment the traffic sending rate is not very high, in operational networks, a network device, such as a cloud gateway or a NFV device, needs to process traffic with the speed of up to terabits per second. Dozens or even hundreds of servers with multiple CPU cores need to be deployed to support the high traffic rate. Hence in practice, Elixir can significantly save the CPU resources, which is extremely important in cloud environment.

Forwarding capability with fixed CPU consumption: We then measure the maximum forwarding rate of the hardware/software hybrid forwarder when there is no packet loss, by using only two CPU cores. For Elixir, TFO and LFP, the two cores are used for both packet forwarding and flow rate measurement; while for PSF, the two cores are both used for packet forwarding. As shown in Table 2, the maximum forwarding rate of Elixir (∼56 Mpps) is almost twice higher
Figure 13: Packet loss rate against different numbers of CPU cores.

Table 2: Maximum forwarding rate of each solution by 2 CPU cores.

	Maximum forwarding rate (Mpps)
Elixir-NIC	56.2
Elixir-switch	56.1
TFO	26.4
LFP-NIC	28.3
LFP-switch	27.6
PSF	9.8

than that of *TFO* and *LFP* (∼27 Mpps). It indicates that, by burst-aware offloading, Elixir makes much higher utilization of the hardware forwarding capability. *PSF* has the lowest maximum forwarding rate (∼9.8 Mpps), since it does not leverage hardware offloading at all.

Latency, queue size and packet loss rate: We also compare Elixir with TFO, LFP and PSF by measuring the per-packet latency, software queue size and the packet loss rate if using two CPU cores at the forwarder. We test two different scenarios for these solutions. In the first case, for each solution the sender generates the highest-speed traffic if there is no packet loss at the forwarder. Specifically, the average sending rates of Elixir, TFO, LFP and PSF are 56.15 Mpps, 26.40 Mpps, 28.0Mpps and 9.80 Mpps, respectively. In the second case, a fixed sending rate of 56.15 Mpps is set for each solution, which is the maximum traffic rate for Elixir to avoid packet loss in the software.

Table 1 shows the results. In the first case, we find that Elixir has larger average latency and larger average queue size than TFO and LFP in the same hardware, since the traffic sending rate of Elixir is more than twice that of TFO and LFP. However, even in this case, the tail latency and tail queue size

of Elixir are orders-of-magnitude lower than that of TFO and LFP, due to the capability to timely detect and offload bursty flows. The gap is even amplified in the second case, where the same traffic sending rate is applied to all these solutions. Specifically, the tail latency of Elixir in the second case is ∼97.63% lower compared with TFO and ∼97.61% lower compared with LFP.

6 Related Works

Hardware/software hybrid flow table management: Previous works on hardware/software hybrid flow table management focus on two aspects, *i.e.* the application of the hybrid flow table and reasonable separation of the flow table between the hardware and software.

For the former aspect, most works focus on designing a network application based on the hybrid flow table [2, 31, 55]. TEA [31] designs a system architecture to enable programmable switches to query large virtual tables built on external DRAM. FlexGate [55] design a getaway to offload most of the traffic by the principle of traffic skewness. VPN Gateway [2] designs a getaway that can connect hundreds of enterprises to their thousands of VMs on the cloud.

The latter aspect is closer to Elixir, *i.e.* managing the hybrid flow table by splitting the flow table between the hardware and software [15, 29, 61]. TFO [61] leverages traffic skewness to split the flow table. CacheFlow [29] leverages traffic skewness and handles the dependencies between rules with overlapping patterns when splitting the flow table. LFP [15] introduces a machine-learning based approach to predict large flows with the first packet of each flow, and offload the predicted large flows. Hence, previous works on flow table splitting primarily focus on identifying and exchanging large flows between the hardware and software. Differently, Elixir pays special attention to bursty flows, and takes both large flows and bursty flows into consideration, which can make better utilization of the hardware resources compared to previous burst-oblivious solutions.

Traffic measurement to identify large flows and bursty flows: A line of previous works focus on traffic measurement to identify large flows [21, 23, 36, 41, 68, 69, 72] or bursty flows [9, 10].

For the large flow identification, they primarily adopt two kinds of approaches, which use exponentially decay and a sliding window separately. The works that employ a sliding window [6, 21, 66] record the flow sizes in a time window and update the flow sizes periodically. The works that adopt exponentially decay [11, 44, 62] apply a decay function which assigns weights to flow sizes based on their ages, and the history of the flow sizes is fading away. The flow sizes recorded by these approaches are used to identify large flows.

The identification of bursty flows is primarily based on a sliding window [9, 10], because exponentially decay is too coarse-grained to measure the fine-grained queue size. ConQuest [9] and Snappy [10] employ multiple snapshots (sketches) to record the flow sizes in a sliding window. They slide the window and reset the sketches periodically to measure the number of packets in the queue.

Elixir also identifies the large flows and bursty flows using an identification window with fixed size. Different from previous works, the large flows and bursty flows should be measured in hardware/software at the same time, which is achieved by sampling and hardware counters. Moreover, Elixir decouples the replacement window from the identification window due to system limitations, which is not considered by previous works.

NFV Optimization: Existing works on NFV optimization include *e.g.* elastic scaling [28, 57, 65], NFV chaining [51, 63], management [8, 51], hardware acceleration [18, 20, 22, 26, 27, 30, 34, 35, 40, 45–47, 53–55, 67], *etc.*. The works on hardware acceleration can be divided into two major directions: one is to offload all the network functions to the hardware with NICs [22, 30, 34, 35, 40, 46, 47, 54], switches [26, 27, 45, 47, 67] or GPUs [20], while the other is to only offload flow table entries to the hardware [2, 15, 29, 31, 55, 61]. Elixir can be applied in the latter case of hardware acceleration and make much higher utilization of the hardware capability than the state-of-the-art solutions.

Flow table compression and optimization: Many recent efforts have been taken on how to improve the utilization efficiency of flow table storage [4, 16, 32, 37, 38, 42, 59, 64, 71] and how to improve the lookup speed of the flow table [3, 14, 16, 32, 37, 38, 42, 58, 71]. They focus on the optimization of the organization of a single flow table. Differently, Elixir focuses on the management of both hardware and software flow tables to make better utilization of the hardware resources.

7 Conclusion

In this paper we design Elixir, a high-performance and low-cost approach to managing hardware/software hybrid flow tables. Compared with previous solutions which only offload large flows to the hardware, Elixir takes both large flows and bursty flows into consideration. Specifically, Elixir combines both sampling-based mechanism and counter-based mechanism for large flow and bursty flow rate measurement, separates the replacement processes of large flows and bursty flows, and decouples the identification window and the replacement window. By these techniques, Elixir not only considerably saves CPU resources required for software forwarding, but also achieves much lower tail forwarding latency.

Abstract

Bandwidth allocation and performance isolation are crucial to achieving network virtualization and guaranteeing service quality in data centers as well as other network systems. Weighted Fair Queuing (WFQ) can achieve customized bandwidth allocation and flow isolation; however, its implementation in large-scale high-speed network systems is very challenging due to the high complexity of the scheduling and the large number of queues required.

This paper proposes Gearbox, a scheduler primitive for next-generation programmable switches and smart NICs that practically approximates WFQ. Gearbox consists of a logical hierarchy of queuing levels, which accommodate a wide range of packet departure times using a relatively small number of FIFOs. Gearbox's enqueue and dequeue operations have $O(1)$ time complexity, which makes it suitable to cope with high-speed line rates. Gearbox provides its simplicity and performance advantages by allowing slight discrepancies in packet departure time from strict WFQ. We show that Gearbox's normalized departure time discrepancy is bounded and has a negligible impact on bandwidth allocation and flow completion time (FCT).

We implement Gearbox in NS2 and in VHDL, targeted to a Xilinx Alveo U250 card with an XCVU13P FPGA. The NS2 evaluation results show that Gearbox closely approximates WFQ and achieves weighted max-min fairness in bandwidth allocation as well as flow isolation. Gearbox provides FCT performance comparable to ideal WFQ. The Gearbox FPGA prototype runs at 350MHz and achieves full line rate for 100GbE with packets larger than 123 bytes. Gearbox consumes less than 1% of the FPGA's logic resources and less than 4% of its internal block memory.

1 Introduction

Bandwidth allocation and isolation are key to network virtualization in data centers and the performance of network systems (e.g., FCT, packet tail latency, and QoS guarantee). WFQ is an ideal packet scheduling scheme that can achieve bandwidth guaranties and performance isolation, as well as other objectives, such as minimizing average FCT and reducing tail packet latency.

However, it is very challenging to implement a WFQ packet scheduler in large-scale high-speed network systems (e.g., systems with millions of active flows and link capacities of hundreds of Gbps). Although several hardware schedulers have been proposed in the past to sort or sequence packets based on their departure times, most of them do not scale well with system size [8] [9] [10] [4] [17], except for a few cutting-edge SoC chips [11] [5]. Push-in First-out (PIFO) [27] [28] is a viable solution but it does not scale easily due to the large number of parallel rank comparisons. More recent works such as AFQ [24] and PCQ [25] are based on the idea of calendar queues [7] [31] and have been implemented on emerging programmable switches. However, to provide the packet serving order of an ideal scheduler, AFQ requires a large number of queues while PCQ suffers from additional memory accesses due to frequent packet re-circulation and packet migration between queues.

We observe that by allowing a slight packet departure order skew in the WFQ, we have the opportunity to greatly simplify its implementation. We define departure time discrepancy (DTD) as the difference between the system time when a packet is served and its departure time assigned by WFQ and normalized DTD as DTD normalized to the expected delay [1]. In fact, packets with different expected delays in ideal WFQ scheduling have different tolerances to such DTD. Packets with longer expected delays can tolerate larger DTD than those with shorter expected delays. By taking advantage of this observation, we propose a new packet scheduler, called Gearbox, that approximates WFQ with a bounded normalized packet DTD. Gearbox adopts the idea of calendar queues [7] [31] and places packets with different expected delays in different logical levels of the calendar queues upon their arrival. When implemented physically, the queues are in fact individual FIFOs arranged into independent groupings. Gearbox can accommodate a very large range of departure times while using a relatively small number of FIFOs. The simplicity of Gearbox's approach makes it suitable for implementation on next-gen programmable switches as well as smart NICs which typically include FPGAs [15]. Note that by changing the 'departure time' in WFQ to other priority ranks calculated by other scheduling schemes (e.g., re-

[1]The departure time refers to the virtual departure time in WFQ [14] [22] [23]. The system time refers to the virtual system time in WFQ. When all the admitted flows are active, the virtual system time runs as fast as the real time.

maining flow size in pFabric [2]), Gearbox can approximate other scheduling schemes as a programmable scheduler. We summarize the contributions of this paper as follows:

- **Provide a close approximation of WFQ with bounded normalized DTD for packets.** Gearbox schedules packets with different expected delays using calendar queues with different granularities. Such tiered granularity allows Gearbox to closely approximate ideal WFQ with a relatively small number of FIFOs while guaranteeing a bounded normalized DTD.

- **Offer scalability with simple implementation.** Gearbox is implemented using queues (FIFOs) from a flat array that are arranged into logical levels. This non-hierarchical FIFO-based physical implementation allows Gearbox to admit a large number of packets and does not presume the existence of queue hierarchy in next-gen programmable switches [24] [25].

- **Implement Gearbox in NS2 with extensive packet-based evaluations.** We implement Gearbox in NS2 [21] and perform extensive packet-based evaluations. The results show that Gearbox closely approximates ideal WFQ and achieves a good weighted max-min fairness with per-flow isolation even in a short time scale. Our simulations based on a fat-tree topology show that Gearbox has an FCT performance closely matching the ideal WFQ using a PIFO.

- **Implement Gearbox in VHDL targeting an FPGA.** We implement a Gearbox VHDL prototype and target a Xilinx Alveo U250 FPGA card with a mid-speed grade XCVU13P FPGA. The Gearbox prototype runs at 350MHz and reaches full 100GbE line rate with packets larger than 123 bytes[2]. Based on the implementation report, Gearbox uses less than 1% of the target FPGA logic resources and less than 4% of its block random access memories (BRAM) as detailed further in Section 4.

The rest of the paper is organized as follows. Section 2 introduces the background and motivation of our work. Section 3 presents the detailed mechanism of the Gearbox scheduler and its extensions. Section 4 presents NS2 evaluation and the Gearbox hardware prototype. We discuss related works in Section 5 and conclude the paper in Section 6.

2 Background and Motivation

2.1 Weighted Fair Queuing

Bandwidth allocation and isolation are critical in data centers as well as other network systems [13] [18] [30] [3] [19].

These attributes are also essential to network performance such as max-min fairness, FCT, and tail latency [20].

WFQ [14] [22] [23] is the most effective algorithm to allocate bandwidth among flows and provide per-flow isolation. WFQ assigns a departure time to each packet and guarantees bandwidth allocation by scheduling packets in ascending order of their departure time[3]. For each packet scheduled by WFQ, its expected delay is its packet size divided by its assigned rate provided that the flow's traffic has been shaped. The expected delay is equal to the difference between the assigned departure time and the system time when the packet arrives.

2.2 Challenges of a WFQ Packet Scheduler

The major challenge of implementing WFQ on high-speed switches is the limited time to process each packet. For 64-byte packets, a scheduler for a 100GbE link has a processing time of only 6.72 ns[4]. In addition, sorting packets according to their departure time usually has a time complexity of $O(logN)$ [12], where N is the number of total packets or flows and could be on the order of several thousands. Maintaining a sorted list of packets in the limited packet processing time on high-speed links is very challenging.

An ASIC-based hardware sorter called Sequencer [8] [9] [10] inserts each arriving packet into a proper position in a queue according to its departure time. However, the Sequencer is not very scalable due to its high power consumption and chip area cost to support the parallel comparison of every arriving packet's departure time to all others' in the queue. The limited scalability of Sequencer precludes it from being used in a typical shared-memory switch in a data center [6] (e.g., with buffer size of ∼60K packets). The pipeline heap (P-heap) [4] [17] implements a WFQ scheduler with better scalability, but it is required for each output port, which results in significant chip area consumption [27], making a P-heap based WFQ scheduler on commodity switches less practical. Recent work on Pushed-in First-out (PIFO) [27] [28] performs parallel packet rank comparisons (similar to above-mentioned Scheduler), which limits its applicability in large high-speed switches.

A calendar queue, introduced by Randy Brown [7] and used in Timer Wheels [31] and used in Approximate Fair Queuing (AFQ) [24] and Programmable Calendar Queues (PCQ) [25], is scalable due to its implementation simplicity (only uses FIFOs). As a trade-off, calendar queues relax the packet sorting order compared to an ideal WFQ scheduler. Unlike in ideal WFQ, a calendar queue only sorts packets approximately in the ascending order of their departure times

---

[3]In a WFQ scheduler, the packet with the smallest departure time leaves the scheduler first.

[4]It is possible to reduce the scheduling rate by using input queuing to combine small packets into a single larger packet. E.g., two 64-byte packets belonging to the same flow can be scheduled as a single 128-byte packet.

---

[2]The VHDL design runs at 350 MHz in the target FPGA and performs enqueues and dequeues every 4 clock cycles, sustaining a packet rate of 87.5 Mpkts/sec. For Ethernet with a Preamble of 8 bytes and IFG of 12 bytes, the line bit rate for 123-byte packets is: $87.5M \times (8+123+12) \times 8 \approx 100Gb/s$.

since its accuracy is limited by the granularity of the sorting buckets. Moreover, calendar queues also suffer from calendar range overflow when the available number of queues cannot accommodate the wide range of departure times. To address the range overflow problem, modifications to calendar queues have been proposed to accept packets with larger departure times instead of dropping them [7][25]. These modifications consist of recirculating out-of-range packets to the end of the queues to delay them until they reach their departure times. When implemented on high-speed switches, calendar queue packet schedulers with packet recirculation impose additional demands on memory bandwidth due to the accesses for both incoming and recirculated packets. We discuss this further in Section 2.4.

2.3 Granularity of the Scheduler and Departure Time Discrepancy

The calendar queue scheduler trades some packet serving order accuracy for simplicity and scalability. Rather than sorting packets perfectly in the ascending order of their departure times, the calendar queue scheduler only sorts packets approximately compared to ideal WFQ. This approximation is due to the FIFO-based structure of the calendar queue [7]: a calendar queue only sorts packets by placing them into different FIFOs or buckets. Each FIFO in a calendar queue cannot differentiate the departure times of the packets in it. Here we quantify the scheduling precision of a calendar queue scheduler as the 'granularity of the scheduler'.

Granularity of the scheduler: the minimal departure time difference that a scheduler can discriminate, noted as g.

Consider the example in Figure 1. For the scheduler in Figure 1(a), each queue represents one virtual time unit and the scheduler can discriminate between the departure times with a difference of 1, which means it has a granularity $g = 1$. The scheduler in Figure 1(b) applies a coarser granularity $g = 10$. This scheduler can only discriminate between packet departure times based on the tens digit of their departure time.

With tiered granularities, calendar queue schedulers sort packets into different approximate orders when compared with ideal WFQ. We formally define the concept of 'departure time discrepancy (DTD)' to quantify the difference between the approximate serving order and that of ideal WFQ.

Departure time discrepancy (DTD): the difference between the system time when a packet leaves the scheduler and its departure time as scheduled by WFQ. We denote the k^{th} packet in flow i as $P_{(i,k)}$ and its DTD as $d_{(i,k)}$.

$$d_{(i,k)} = \begin{cases} D_{(i,k)} - F_{(i,k)} & , D_{(i,k)} > F_{(i,k)} \\ 0 & , \text{otherwise} \end{cases} \quad (1)$$

Here $F_{(i,k)}$ is the ideal departure time as calculated by the

(a) Scheduler granularity = 1   (b) Scheduler granularity = 10

Figure 1: Different granularities

WFQ scheduler for $P_{(i,k)}$ and $D_{(i,k)}$ is the actual departure time of packet $P_{(i,k)}$.

DTD shows the difference of the packet serving order between a calendar queue scheduler and an ideal WFQ. It indicates how well a calendar queue scheduler approximates an ideal WFQ from a packet's perspective. A small DTD indicates that the scheduler approximates an ideal WFQ closely and a large DTD, that a packet may experience a delay larger than its expected delay, which further leads to increased FCT or other consequences.

For a calendar-queue-based scheduler with a limited number of queues and fixed granularity [24] [25], different levels of granularity have pros and cons. Schedulers with finer granularity provide smaller DTDs. However, they only accommodate a narrow range of departure times and are therefore more prone to calendar range overflow. A rotating calendar scheduler consisting of M queues covers only $M * g$ future virtual time units. Packets with departure times beyond this bound will be dropped due to calendar range overflow, as shown in Figure 1(a). With a small number of available queues, we can consider the scheduler as having a shallow buffer, which is easy to overflow. For services requiring a certain amount of burstiness tolerance, this shallow buffer could lead to frequent packet drops. Furthermore, flows assigned relatively low bandwidths, which lead to large departure times, could experience excessive packet drops. This makes such fine-grained schedulers unsuitable to handle large variations in weighted bandwidth allocation. Schedulers with a coarser granularity alleviate the calendar range overflow issue by covering a wider range of departure times in the future. However, one obvious downside of using a coarse granularity is larger DTDs. Consequently, packets in the same queue may not be scheduled according to the order of their departure times. For example, in Figure 1(b) the green packet departs after packets with larger departure times in the coarse-grained scheduler.

As shown in the examples in Figure 1, scheduler granularity leads to a trade-off between fewer calendar range overflows and smaller DTDs.

2.4 Normalized DTD

How do we determine an appropriate granularity for the scheduler? One could argue that it is always better to have a scheduler with finer granularity. But is it necessary to achieve such a small DTD for all packets?

If we need to maintain a fine granularity while covering a wide departure time range, the total number of queues required would become very large. This design approach conflicts with the goal of a simple implementation. The time complexity of managing thousands of queues is very high and most switches may not have the required number of queues.

Another approach for providing fine scheduler granularity while preventing calendar range overflow is packet recirculation. The classic calendar queue [7] and Timer Wheel [31] place all packets into their queues. Packets scheduled too far in the future are simply enqueued in a queue roughly determined by the departure time modulo the total number of queues, and recirculated before their departure times become due. This will lead to additional memory bandwidth consumption, where memory bandwidth is very often the limiting factor in a networking equipment [32] [16]. Excessive packet recirculation can use up valuable shared memory bandwidth and lead to a significant drop in switch throughput. A recent work, PCQ [25], implements an alternative packet recirculation scheme. PCQ arranges calendar queues in multiple levels with different granularities. When PCQ finishes serving all the packets in the lower level, it recirculates and deposits all packets from a head queue in the higher level to appropriate queues in the lower level. Such a packet recirculation scheme can still lead to throughput reduction on high-speed switches.

Based on the above analysis, providing fine granularity with a wide range of packet departure times is resource intensive. But is it really necessary? We observe that packets have different tolerances to DTDs depending on their expected delays upon arrival as mentioned in Section 2.1. Packets with a smaller expected delay usually expect to be served shortly and are sensitive to small differences in the scheduling order. For these packets, a fine-grained scheduler is necessary to guarantee a small DTD. However, packets with larger departure times upon arrival can tolerate larger DTDs. These packets usually belong to flows with low assigned bandwidths: WFQ assigns these packets with large departure times to achieve bandwidth weighted max-min fairness in the long run. For these packets, their large expected delay makes it unnecessary to schedule them with fine granularity.

According to the above analysis, it is more appropriate to consider a packet's DTD based on its tolerance to it. We therefore normalize a packet's DTD to its expected delay.

Normalized DTD: the DTD normalized to the packet's expected delay, noted as $d_{n(i,k)}$.

Figure 2: Gearbox System-level Application

$$d_{n(i,k)} = \begin{cases} \frac{D_{(i,k)} - F_{(i,k)}}{F_{(i,k)} - A_{(i,k)}} & , D_{(i,k)} > F_{(i,k)} \\ 0 & , \text{otherwise} \end{cases} \quad (2)$$

Here $A_{(i,k)}$ is the system time t_s when packet $P_{(i,k)}$ arrives at the scheduler, $F_{(i,k)}$ is the ideal departure time for packet $P_{(i,k)}$ determined by the WFQ scheduler, and $D_{(i,k)}$ is the actual departure time of packet $P_{(i,k)}$.

For example, say that packet $P_{(A,1)}$ and packet $P_{(B,1)}$ arrive at the scheduler when system time $t_s = 10$. Packet $P_{(A,1)}$ has an ideal departure time $F_{(A,1)} = 11$ and packet $P_{(B,1)}$ has an ideal departure time $F_{(B,1)} = 91$. Assume the scheduler applies a coarse granularity $g = 10$. Due to the coarse granularity, packet $P_{(A,1)}$ leaves the scheduler at $t_s = 19$ and packet $P_{(B,1)}$ leaves the scheduler at $t_s = 99$. Both of the packets have a DTD of 8. Although the two packets have the same DTD, they have different tolerances to it. The expected delay of packet $P_{(A,1)}$ and $P_{(B,1)}$ is $11 - 10 = 1$ and $91 - 10 = 81$ respectively. When we evaluate their normalized DTD, we have $d_{n(A,1)} = 8/1 = 8$ and $d_{n(B,1)} = 8/81 \approx 0.1$. This means packet $P_{(A,1)}$ is experiencing a delay that is 8 times its expected delay while packet $P_{(B,1)}$ has a delay only 1.1 times its expected delay. This indicates such granularity is appropriate for packet $P_{(B,1)}$ but is too coarse for packet $P_{(A,1)}$. This example shows that it is difficult to find an appropriate fixed granularity to schedule packets with different expected delays while satisfying DTD bounds.

3 Gearbox: Hierarchical Packet Scheduler

3.1 Basic Idea of Gearbox

Based on our analysis in Section 2.4, it is more appropriate to guarantee different DTD bounds for packets with different expected delays. In this case, we need a scheduler with flexible granularity to serve different packets. Thus, the scheduler must guarantee a low normalized DTD while keeping the implementation simple. We introduce Gearbox, a hierarchical packet scheduler that closely approximates WFQ and is simple to implement.

Figure 2 shows a simplified system-level application of Gearbox. Incoming packets are stored in the Packet Buffer. The packet header is sent to the packet Parser & Classifier to identify the flow (e.g., using 5-tuple classification) and determine the packet length. The Departure Time Calculator com-
Figure 3: Gearbox: Hierarchical FIFO-based scheduler

Table 1: TERMS AND NOTATIONS

Notation	Description
$P_{(i,k)}$	k^{th} packet in flow i
$F_{(i,k)}$	Departure time of packet $P_{(i,k)}$ assigned by WFQ
$A_{(i,k)}$	System time when packet $P_{(i,k)}$ arrives at the scheduler
$D_{(i,k)}$	System time when packet $P_{(i,k)}$ leaves the scheduler
$d_{(i,k)}$	Departure time discrepancy (DTD) of packet $P_{(i,k)}$
$d_n(i,k)$	Normalized DTD of packet $P_{(i,k)}$
t_s	Current system virtual time
L	Total levels of the scheduler
M_l	Total number of FIFOs at level l
g_l	Granularity of level l
$Q_{(l,f)}$	FIFO f at level l

putes the packet's departure time and forwards it along with the packet descriptor (length, departure time, and enqueue Packet Pointer from Packet Buffer) to Gearbox to enqueue the packet. Upon request from a controller (not shown) Gearbox dequeues stored packet descriptors according to a calendar order described in detail below and forwards the descriptors to the Packet Buffer that outputs the packets. We further present the smart NIC use case and multi-pipeline use case of Gearbox in Appendix B.

Gearbox arranges FIFO-based calendar queues into 'logical levels' with different granularities, achieving the benefits of calendar queue schedulers with different granularities to serve packets with different expected delays. Lower logical levels with finer granularity provide smaller DTD for packets with departure times that are close to current system time upon arrival. Higher logical levels with coarser granularity serve packets with large departure times and cover a wider departure time range, reducing packet loss due to calendar range overflow. By providing tiered scheduling granularity, Gearbox guarantees a low normalized DTD for all packets with a relatively small number of queues. Moreover, Gearbox eliminates packet recirculation by directly serving packets at all levels based on our 'Compound FIFO' concept introduced in Section 3.2. This eliminates the additional memory accesses due to recirculation and allows Gearbox to achieve a high packet processing rate efficiently.

Figure 3 shows an example of the Gearbox hierarchical scheduler. Consider a scheduler with 30 available queues. Gearbox arranges them into 3 logical levels with different granularities, each logical level containing 10 queues. Level 1 has the finest granularity $g_1 = 1$, level 2 has a coarser granularity, $g_2 = 10$ and level 3 has the coarsest granularity, $g_3 = 100$. In this example, packets with a departure time within 10 virtual time units in the future upon arrival are enqueued in level 1 and are scheduled with the granularity of $g = 1$. Packets with a departure time larger than 10 but smaller than 100 virtual time units in the future upon arrival are enqueued in level 2. Other packets with departure time between 100 and 1000 virtual time units in the future upon

arrival are enqueued in level 3.

Note that the 'levels' in Gearbox are logical concepts. When implemented physically, they are in fact individual queues (FIFOs) arranged into independent groupings, which means Gearbox only requires a single level of queues in the hardware. We'll further discuss this in Sections 3.2 and 3.3. As a result, Gearbox can be implemented on devices that do not support hierarchy.

In section 3.4, we prove that Gearbox guarantees a low normalized DTD for all packets. Our evaluation shows that Gearbox closely approximates ideal WFQ from a user's point of view. Gearbox can be thought of as a clock. The lower logical level with finer granularity is like the second hand, serving packets in units of seconds. The higher logical levels are like the minute hand or the hour hand, admitting more packets with a larger departure time and serving them with a coarser granularity. Each logical level of the scheduler cooperates to schedule packets with different granularities, which makes the scheduler just like a gearbox shifting between different gears.

To better illustrate the detailed schemes in Gearbox, we summarize the related concepts and notations in Table 1. We further generalize the multi-level architecture of the Gearbox scheduler. The scheduler contains L logical levels of calendar queues, each one with a different granularity g_l. Each logical level of the scheduler contains M_l FIFOs and covers a departure time range of $[t_s, t_s + (M_l * g_l))$.

3.2 Compound FIFO

Researchers have tried to arrange the calendar queues in hierarchical structures, however, their implementations are not suitable for the ultra-high-speed switches due to packet recirculation and the short packet processing time.

To eliminate packet re-circulation, Gearbox applies the concept of a 'Compound FIFO' to directly schedule packets in different levels efficiently. As Figure 3 shows, the compound FIFO consists of the current serving FIFO in each level. In the example, the compound FIFO consists of $FIFO1$ at level 3, $FIFO2$ at level 2 and $FIFO3$ at level 1,

representing the current system time $t_s = 123$. Note that all the FIFOs in the compound FIFO cover the current system time t_s, which means that the individual FIFOs that make up the compound FIFO possibly contain packets that need to be served at the current system time.

Gearbox serves packets in the compound FIFO using a factor that is inversely proportional to the granularity of the level that each queue belongs to. Gearbox serves packets from the lowest-level queue to the highest-level queue in the compound FIFO. Since the lowest-level has the finest granularity, the departure time of all the packets in this queue equals the current system time t_s. Gearbox serves all the packets in the queue in the lowest level. After draining packets in the lowest-level queue, Gearbox starts to serve the queue at the next higher level. At each of the higher levels, we serve a number of bytes (rounded up to a whole number of packets) that is inversely proportional to the level's granularity g_l [5]. Gearbox finishes serving the compound FIFO when it finishes serving all the queues within it according to their levels. After serving the compound FIFO, Gearbox updates current system time t_s to the next non-empty compound FIFO.

As an illustration of serving packets from the different levels, the FIFOs in the pink box in Figure 3 are dequeued as follows. Gearbox first drains all the packets in $FIFO3$ at level 1. After that, since level 2 has the granularity of $g_2 = 10$ and $FIFO2$ at level 2 covers the time range from 120 to 129, Gearbox serves $1/10$ packets in this queue. Likewise, Gearbox serves $1/100$ of the packets in $FIFO1$ at level 3. After serving the correct proportion of packets in the queue at each level, Gearbox increases its current system time t_s by 1 and updates the compound FIFO based on the new system time $t_s = 124$.

The key contribution of the 'Compound FIFO' is freeing the scheduler from packet recirculation. By directly serving queues in different levels using a factor that inversely proportional to their granularity, Gearbox eliminates the need to recirculate packets. This means Gearbox's dequeue process is as simple as popping from a FIFO. This allows Gearbox to easily achieve a high packet processing rates on core switches. The trade-off is increased DTD in the higher levels.

3.3 Enqueue and Dequeue Processes

Enqueue Process The Gearbox packet enqueue process is straightforward. To enqueue a packet, Gearbox needs to determine the correct level and the destination FIFO for the arriving packet. Gearbox first finds the level to enqueue using the difference between the current system time t_s and the departure time of the packet $F_{(i,k)}$. The packet will enqueue

---

---

the lowest possible level that covers this interval. After finding the enqueue level, Gearbox simply divides the interval mentioned above by granularity g_l at this level to find the corresponding FIFO to enqueue.

Figure 3 shows an example of Gearbox's enqueue process. In the example, Gearbox has 3 levels covering the departure time range $[t_s, t_s + 9]$, $[t_s, t_s + 99]$, $[t_s, t_s + 999]$, respectively. The pink packet with a departure time of 135, arrives at the scheduler when $t_s = 123$. Upon the packet's arrival, the scheduler calculates the interval $F_{(i,k)} - t_s = 12$. This interval falls into the virtual time range covered by level 2. When we divide the interval 12 by the granularity g_2, we have $\lfloor 12/10 \rfloor = 1$, which indicates that this packet is enqueued in the FIFO next to the current serving FIFO in this level. The enqueue process is summarized in Algorithm 1.

Algorithm 1 Enqueue Process

1: **function** ENQUEUE PACKET($P_{(i,k)}$)
2:     **for** level l from 1 to L **do**
3:         **if** $\lceil (F_{(i,k)} - t_s)/g_l \rceil \le M_l$ **then**
4:             $f = \lfloor (F_{(i,k)} - t_s)/g_l \rfloor$
5:             $P_{(i,k)}$ enqueue f^{th} FIFO following the current serving FIFO
6:             **return**
7:     Drop packet $P_{(i,k)}$

Dequeue Process As we have introduced the compound FIFO in *Section 3.2*, the dequeue process of Gearbox was described above as serving the compound FIFO. We generalize Gearbox's dequeue process with the pseudo-code in Algorithm 2, where f_l is the FIFO of level l in the compound FIFO

Algorithm 2 Dequeue Process

1: **function** DEQUEUE PROCESS
2:     **for** level l from 1 to L **do**
3:         **if** $Q_{(l,f_l)}$ is not empty **then**
4:             dequeue $Q_{(l,f_l)}$ up to $Size(Q_{(l,f_l)})/g_l$

3.4 Normalized DTD Analysis

We previously defined the normalized DTD $d_{n(i,k)}$ as the DTD normalized to the packet's expected delay in equation (2). Now we need to determine its bound in Gearbox. Based on the above expression, the maximum value of $d_{n(i,k)}$ occurs when DTD is at the maximum value and the expected delay is at the minimum value. For a packet at level l, the maximum DTD equals the level's granularity g_l. Then we have:

$$\max\{D_{(i,k)} - F_{(i,k)}\} = g_l \qquad (3)$$

We need to find the minimal expected packet delay possible at level l. Based on the enqueue process described in section 3.3, packets enqueue at different levels based on their expected delay. Only packets with an expected delay between g_l and $g_l * M_l$ will enqueue at level l. Therefore, we have minimal expected delay:

$$\min\{F_{(i,k)} - A_{(i,k)}\} = g_l \qquad (4)$$

From equation (3) and (4), we have maximum delay:

$$\max\{D_{(i,k)} - A_{(i,k)}\} = 2g_l \qquad (5)$$

Then from (4) and (5) we have maximum normalized DTD:

$$\max\{d_{n(i,k)}\} = \max\{\frac{D_{(i,k)} - F_{(i,k)}}{F_{(i,k)} - A_{(i,k)}}\} = \frac{2g_l - g_l}{g_l} = 1 \qquad (6)$$

The maximum normalized DTD has an upper bound of 1, which means, in the worst case, that a packet scheduled by Gearbox will have a maximum delay that is twice its expected delay in WFQ. In other words, a packet that expects t microseconds delay in a WFQ scheduler will experience at most $2t$ microseconds delay in Gearbox in the worst case[6]. We evaluate the normalized DTD in actual time using simulations and provide our evaluation results in *Section 4*.

3.5 The Packet Out-of-order Issue

Packets in the hierarchical calendar queue scheduler may experience a packet out-of-order issue. According to the architecture of Gearbox, FIFOs at different levels might cover an overlapping virtual time range. As a result, a packet $P_{(i,k)}$ with a departure time $F_{(i,k)}$ may enqueue at any level of the scheduler, depending on its arrival time $A_{(i,k)}$. Similarly, a subsequent packet $P_{(i,k+1)}$ from the same flow may enqueue at a different level. When two packets from the same flow enqueue in different levels in the scheduler, the relative order of the packets is not deterministic. It is possible that packet $P_{(i,k)}$ leave later than the subsequent packet $P_{(i,k+1)}$ if it is enqueued at a different level in the scheduler, causing the packets to be dequeued out of order.

Figure 4 shows an example of the packet out-of-order issue. In the figure, packets $A1$ and $A2$ arrive at the scheduler when $t_s = 0$. Since both packets have a departure time exceeding $t_s + 9$, they cannot be enqueued at level 1 and are thus enqueued in $FIFO1$ at level 2. Later, the system time t_s updates to $t_s = 10$. A new packet $A3$ from the same flow arrives at the scheduler with a departure time of $F_{(A,3)} = 12$. At this moment, $F_{(A,3)} - t_s = 2 < 10$ and the scheduler places $A3$ in $FIFO2$ at level 1. At this point, packets from flow A

---

[6]The delay discrepancy may be smaller than 2x if all the flows are not active and the packet has an earlier opportunity to be dequeued

Figure 4: The packet out-of-order issue

are placed at different levels. As the scheduler starts to serve packet $A3$ when $t_s = 12$, packets $A1$ and $A2$ are still queued up at the tail of $FIFO1$ at level 2. In this case, packet $A3$ leaves before packets $A1$ and $A2$.

3.6 Solution to the Packet Out-of-order Issue

We introduce two modifications to eliminate the uncertainty in the packet serving order. First, we do not 'wrap around' FIFOs in the same level. This means that after the scheduler drains a FIFO and starts to serve the next one, the drained FIFO does not enqueue any packets until the scheduler finishes serving all the packets in the entire level. Second, we track the 'last packet enqueued level' for each flow, noted as L_i, where i is the flow id. When a new packet $P_{(i,k)}$ arrives at the scheduler, it is enqueued in a level equal to or higher than level L_i.

Let's consider the same example in Figure 4 after applying the solution. When packet $A1$ and $A2$ enqueue level 2 of the scheduler, Gearbox marks flow A's last packet enqueue level as $L_A = 2$. When packet $A3$ arrives at the scheduler, although $F_{(A,3)} - t_s = 2 < 10$, the scheduler will only place packet $A3$ into a level equal or larger than $L_A = 2$. In this case, Gearbox places packet $A3$ in $FIFO1$ at level 2 right after packet $A1$ and $A2$. As a result, it is scheduled after its preceding packets $A1$ and $A2$. Consequently, these modifications eliminate the packet out-of-order issue.

The modifications mentioned above may lead to side effects that could potentially increase the DTD of packets. The flows with input rates higher than their allocated rates will enqueue and stay in a higher level, where they will suffer from a coarser granularity and higher DTD. We further introduce the 'Step-down FIFO', an extension of Gearbox to solve these side effects. We present the details of this extension in Appendix A.

4 Implementation and Evaluation

In this section, we describe the design and implementation of Gearbox in NS2, a packet-based simulator [21], and in VHDL as a hardware prototype (targeted to Xilinx's Alveo U250 card[34]), along with the extensive simulations to evaluate the performance of Gearbox. The two implementations and their associated verification environments enabled us to explore different aspects of Gearbox including its performance in networks, the performance of the hardware prototype, and the hardware resource utilization.

4.1 Packet-based Evaluation

To evaluate Gearbox's performance in a large-scale network topology with real-world data traffic, we implemented Gearbox in NS2 [21] and conducted extensive packet-based simulations.

4.1.1 Evaluation Setup

Network topology We set up two different network topologies in NS2: (1) a single-node star topology for bandwidth allocation and fairness evaluation, and (2) a fat-tree topology to evaluate FCT and normalized DTD.

For the single-node topology, we connect five servers to a switch as shown in Figure 5. All the links have equal bandwidth of 10 Gbps and a delay of $3\mu s$. We later use this simple star topology to form a classic incast traffic pattern to observe the bandwidth share of individual flows and evaluate the fairness of the scheduler.

We built a three-level fat-tree topology for large-scale simulation. As shown in Figure 6, there are 4 Core switches, 8 Aggregation switches, 8 Top-of-Rack (ToR) switches and 256 servers. The links between servers and ToR switches are 10Gbps with 10 ns delay. Other links have a bandwidth of 40Gbps and a $1\mu s$ propagation delay. We apply Gearbox and other scheduler schemes on every ToR/Aggregation/Core switch to evaluate the FCT performance.

Traffic loads We generate empirical traffic workloads based on the datacenter flow size distribution from an operational datacenter that supports web-search service [2]. The traffic follows a heavy tail distribution as Figure 7 shows. The flows arriving in a Poisson process with different arrival
intervals result in different traffic loads. Each flow randomly selects the source and the destination hosts in the topology in a uniform distribution.

Alternative approaches We compare Gearbox with single-level calendar queues [24]. All the schedulers in our evaluation have 56 FIFOs and are evaluated with different granularities as discussed in *section 2.3*. Table 2 provides details of the Gearbox and calendar queue schedulers. We also compared Gearbox with an ideal PIFO-based WFQ scheduler as well as a simple drop tail queue. In our packet-based simulation, all packets have the same size of 1,500 bytes [7] and the number of bytes per virtual time unit is set to 750 bytes (the finest supported granularity).

4.1.2 Single-node Microbenchmark

Gearbox can reach good max-min fairness We observe that Gearbox can reach satisfactory max-min fairness in bandwidth allocation, close to that of PIFO-based WFQ. In

---

[7]In NS2 packet based simulations, packet size is not a factor that affects switch performance.

Table 2: PACKET SCHEDULER SET UP

Packet Scheduler	Granularity
Gearbox	$g_1 = 1, g_2 = 8, g_3 = 64$
CQ-1	$g = 1$
CQ-10	$g = 10$
CQ-100	$g = 100$

Table 3: Flow Weight Sets

Weight Set 1	$1:1:1:1$
Weight Set 2	$2:2:1:1$
Weight Set 3	$50:50:1:1$
Weight Set 4	$100:100:1:1$

our single-node microbenchmark evaluation, we used four TCP flows, each sending traffic to one destination node with different starting times and ending times. Based on the results shown in Figure 8, Gearbox allows the TCP flows to reach a bandwidth max-min fairness with good flow isolation. When a new flow joins, Gearbox quickly adjusts the bandwidth allocated to all the active flows and reaches the max-min fairness. After a flow ends, Gearbox also allows the remaining flows to ramp up quickly.

Normalized Fairness Metric   To better evaluate fairness in bandwidth allocation, we use the Normalized Fairness Metric (NFM). Shreedhar and Varghese first measured fairness in bandwidth allocation using the Fairness Metric (FM) [26]. FM reflects the maximum difference in the number of served bytes between two flows during a time period. By definition, FM's values vary significantly based on the bandwidth assigned to each flow and the total shared bandwidth.

To normalize the influence of this factor, Brent Stephens introduced a better metric: the Normalized Fairness Metric (NFM) [29]. NFM normalizes the Fairness Metric according to the number of bytes that each flow should serve. In a scenario where 4 flows are sharing a link of 4 Mbps with equal weights, each flow is assigned a bandwidth of 1 Mbps. During 1 second, each flow should have 128 kbytes of data served. If the measured Fairness Metric $FM(1sec) = 32kbytes$, then the Normalized Fairness Metric $NFM(1sec) = 32kbytes/128kbytes = 0.25$.

Gearbox has a good NFM even for short time scales. By definition, a lower NFM indicates better fairness in bandwidth allocation. In our evaluation, we observed the NFM of flows with 4 different weight sets (shown in Table 3) in different time scales. From the results shown in Figure 9, Gearbox outperforms coarse-grained calendar queues with different bandwidth allocations. When flows are assigned with weights that differ significantly, the fine-grained calendar queues suffer from packet loss while Gearbox maintains good fairness performance. From the perspective of max-min fairness, Gearbox's performance matches closely that of PIFO-based WFQ.

4.1.3   Large-scale Simulation

We extend our simulation to a three-level fat-tree topology with more servers and higher link rates as described in section 4.1.1. We focus on the normalized FCT performance of different size flows. [8]

Figure 10(a) shows the average normalized FCT across different traffic loads and Figures 10(b) and 10(c) show the average normalized FCT of different size flow groups under 70% and 90% load, respectively. The 95^{th} percentile normalized FCT under various traffic loads is shown in Figure 10(d). Figures 10(e) and 10(f) show the 95^{th} percentile normalized FCT broken down per flow size under 70% and 90% traffic load, respectively.

Short flows benefit from low DTD   Gearbox closely approximates WFQ and provides per-flow isolation, which results in low DTD, a key factor for short flow FCT performance. With WFQ, different flows are isolated from each other and packets from large flows will not block packets from small flows. As we discussed in *section 2.3*, the lower level of Gearbox provides a fine scheduling granularity, guaranteeing that packets from short flows depart according to their departure times without a large discrepancy. Figures 10(b), 10(c), 10(e) and 10(f) show that short flows that are less than 80 kbytes have a small normalized FCT. According to Figure 10, Gearbox can achieve a low normalized FCT close to ideal PIFO-based WFQ and the calendar queue with the finest granularity. On the other hand, packets from short flows would suffer a large DTD in the coarse-grained calendar queues and the drop tail queues.

Short flows consist only of a few packets. Therefore, DTD can cause delays that has a negative effect on their FCT. To further observe the delay of short flows under different scheduler schemes, we measure the average end-to-end delay. As shown in Figure 11, the extra delay in the coarse-grained calendar queues leads to a large normalized FCT for short flows. In contrast, Gearbox has a low delay that is close to that of PIFO-based WFQ.

As stated in *section 3.4*, Gearbox guarantees a low normalized DTD for all packets. We evaluated the normalized DTD of Gearbox [9] as shown in Figure 12. The normalized delay shown in the figure is the actual delay normalized to

---

[8]"Normalized FCT" means a flow's actual FCT normalized to its ideal FCT when no other flows are active in the network.

Figure 10: Normalized FCT in fat-tree topology

the delay of the ideal WFQ using a PIFO. In Figure 12, the red dashed line represents the normalized delay with a value of 1, which indicates that the delay is equal to that of ideal WFQ. The simulation results show that Gearbox has a satisfactory normalized delay that is close to 1 for flows with different sizes, indicating that Gearbox has a delay performance closely matching that of ideal WFQ.

Large flows benefit from low packet loss rate Gearbox not only provides a small normalized FCT for short flows, but it also reduces packet loss and re-transmission for large flows. Thanks to its higher levels, Gearbox can schedule packets with large departure times with a very low drop rate.

Figure 10 shows Gearbox can achieve good normalized FCT performance for mid-sized flows around 200 kbytes or larger. We further measured the average packet loss of different flow groups. As shown in Figure 13, the single-level calendar queues with fine granularity drop packets frequently for the mid-sized and large flows, triggering a large number

of re-transmissions and leading to a high normalized FCT. However, Gearbox and other coarse-grained calendar queues have low packet loss rates that are close to zero. Gearbox reduces packet loss related to calendar range overflows and guarantees a low normalized FCT for mid-sized and large flows.

As shown in the above simulation results, Gearbox combines the benefits of both fine and coarse calendar queue granularities. Consequently, Gearbox provides satisfactory normalized FCT performance for flows with different sizes as discussed in *Section 3*. The evaluation results show that Gearbox provides performance comparable to PIFO-based WFQ.

4.2 Hardware Prototype Design

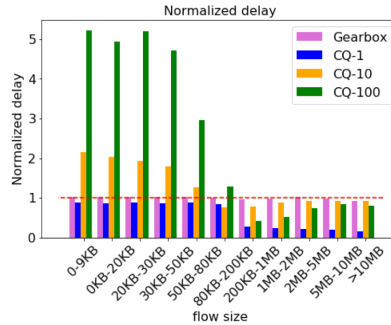
Overview We implemented Gearbox in VHDL with multiple parameters (generics) for easy scalability including:


Figure 11: Average end-to-end delay of short flows

Figure 12: 99^{th} percentile normalized delay

Figure 13: Average packet loss percentage

- Number of levels
- Number of FIFOs per level
- Number of flows
- Other sizing parameters for memories and logic

The VHDL code, test bench, and FPGA implementation files are available at `https://github.com/Gearbox-NSDI/Gearbox_NSDI`

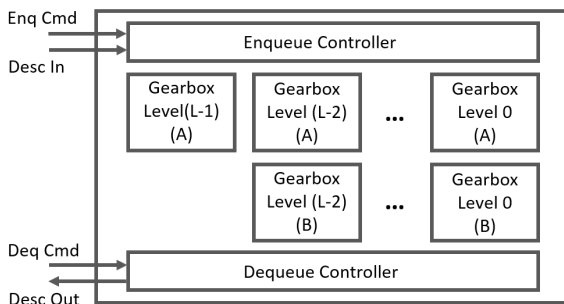
Hardware prototype architecture A high-level block diagram of the VHDL implementation of Gearbox is shown in Figure 14.


Figure 14: Gearbox Block Diagram - VHDL Implementation

At the top level, Gearbox consists of a parameterized number of instances of the Gearbox Level sub-block along with the Enqueue and Dequeue Controller blocks. Each level except the highest consists of two Gearbox Level sub-blocks denoted (A) and (B). The A and B sub-blocks form a ping-pong scheme to guarantee access to a full set of FIFOs (corresponding to virtual time units) while maintaining packet order. The highest level consists only of a single Gearbox Level sub-block because a wraparound of the FIFO index does not cause out-of-order packets.

The Gearbox Level sub-block shown in Figure 15 consists of a parameterized number of FIFOs along with Enqueue and Dequeue logic blocks.

The enqueue and dequeue operations are described below. The packet descriptor is formatted as follows:

Packet Pointer (15)	Address of packet in packet buffer
Packet Length (11)	Packet length in bytes
Packet Time (20)	Packet transmission time, i.e., the time it takes to transmit the packet at the given flow rate
Flow ID (10)	Flow identification number
Packet ID (16)	Packet identification number (used only to detect out of order events)
Figure 15: Gearbox Level - VHDL Implementation

The width of each descriptor subfield is parameterized. The numbers in parentheses denote example widths for a given configuration.

Enqueue Operation Upon receipt of an enqueue command, Gearbox performs the following steps:

1. Calculate the packet's departure time based on the packet transmission time and the system time t_s

2. Determine the enqueue level and enqueue FIFO within that level

3. Store the packet descriptor in the calculated level and FIFO

Gearbox completes an enqueue operation in three clock cycles.

Dequeue Operation   Upon receipt of a dequeue command, Gearbox performs the following steps:

1. Find first non-empty level and FIFO and update the system time t_s

2. Calculate number of bytes to serve from each level

3. Dequeue from each level a number of descriptors to reach or exceed the number of bytes to serve

Gearbox completes a dequeue operation in four clocks when performing steps 1 through 3 and in two clock cycles if performing only step 3 (i.e., dequeuing from each non-empty level once steps 1 and 2 are completed).

Math Operations   The VHDL implementation of Gearbox is scalable using generics that are powers of 2, notably for the number of levels, granularity of each level, and the number of FIFOs within each level. This enables calculations that require division operations to be implemented using bit shifting or truncation, which are much more efficiently implemented in logic gates.

Targeting to an FPGA   We targeted the Gearbox VHDL design configured with 4 levels and 16 FIFOs per level, 256 locations (packet descriptors) per FIFO, and 1K flows to a Xilinx Alveo U250 board [34], which uses an UltraScale+ VU13P FPGA with mid-speed grade. Using Vivado 2020.2 [33], we obtained the utilization and performance shown in Table 4.

Table 4: FPGA prototype utilization and performance

	Frequency	LUTs	FFs	BRAM
Units	350 MHz	12331	9953	96
Device Util Pct		0.71%	0.29%	3.6%

With an enqueue and a dequeue every four clocks, the design sustains a packet rate of $350 \div 4 = 87.5$ Mpkts/sec, which is equivalent to a line rate of 100 Gigabit Ethernet for 123-byte packets or larger, taking into account a Preamble of 8 bytes and an IFG of 12 bytes.

5   Related Work

After the proposal of numerous bandwidth allocation algorithms such as WFQ, PGPS, and SCFQ, academia and industry have worked to implement packet schedulers supporting these algorithms. This trend first begins with the ASIC design. In the 1990s, the Sequencer [8] [9] [10] was an ASIC-based hardware packet scheduler that sorts packets into ascending order based on their departure time with limited scalability. In the 2000s, a specialized data structure:

pipeline heap (P-heap) [4] [17] provided fine-grained priority queues in hardware, which improves the scalability but is required for each egress port [27] [28] and therefore uses significant chip area on high-speed switches. The recent work PIFO [27] [28] provides a programmable packet scheduler, which has a very small chip area overhead and is relatively easy to implement. However, it requires special hardware support (such as TCAM) and has limited scalability.

The limitations of the ASIC-based hardware packet schedulers we mentioned in section 2 motivated research in approximate schedulers based on strict-priority queues. Among them are the Approximate Fair Queuing (AFQ) [24] and Programmable Calendar Queues (PCQ) [25]. AFQ and PCQ perform well in bandwidth allocation with the same weights. However, when flow weights vary over a wide range, AFQ and PCQ's fixed granularity leads to low scheduling precision or packet drops. The authors of PCQ discuss a hierarchical architecture in their paper, but its dequeuing scheme might lead to starvation of flows in the lower level. SP-PIFO [1] is another recent work that uses a unique algorithm to adjust the priority between FIFOs to minimize scheduling errors. However, SP-PIFO may cause misordering of packets within a single flow, which would lead to problems for TCP-based flows.

6   Conclusion

In this paper, we propose Gearbox, a hierarchical packet scheduler that practically approximates WFQ. Gearbox is a FIFO-based packet scheduler targeted to next-gen programmable switches and smart NICs. Its tiered granularity allows Gearbox to achieve an adequate normalized DTD and FCT performance with a relatively small number of queues. Gearbox eliminates packet recirculation and has a streamlined operation that allows it to achieve high packet processing speed. From our evaluation, Gearbox achieves weighted max-min fairness in bandwidth allocation and FCT performance comparable to that of ideal WFQ. We implement Gearbox in an NS2 simulator and a VHDL-based hardware prototype, targeting a Xilinx ALVEO U250 FPGA card. Our Gearbox hardware prototype runs at 350 MHz, which is equivalent to a maximum throughput of 58.8 Gbps with 64-byte packets over 100GbE and full line rate 100GbE with packets larger than 123 bytes.

Appendix

A Step-down FIFO

The solution to the packet out-of-order issue in Section 3.6 may increase the DTD of specific flows. Normally, packets will enqueue at the appropriate level with a granularity that is appropriate for their expected delays. As long as the packets from a flow arrive at the allocated rate, its packets will always enqueue at the appropriate level with a guaranteed low DTD. However, when a flow's input data rate exceeds its allocated bandwidth, its packets may queue up at higher levels. As the scheme in Section 3.6 maintains the 'Last packet enqueued level' L_i, such flows would only enqueue their subsequent packets in the higher levels from that point on. As previously discussed, when packets that belong to a lower level enqueue at a higher level, they suffer from a coarser granularity and higher DTD. This leads to larger packet delays and increases FCT. In this case, flows need to step back to the lower level in which they are supposed to enqueue so they can restore the lower DTD. Is it possible for a flow that queues up to a higher level to step down to a lower level when its arrival rate decreases to its admitted bandwidth?

The answer is yes: we introduce the 'Step-down FIFO', which allows flows at a higher level to go to a lower level. To understand the design of the Step-down FIFO, we must first understand why we need to enqueue packets into a higher level. According to Section 3.4, we can secure the serving order of packets as long as we serve them with the same granularity. In other words, if we can serve packets at the higher level with the same granularity at the lower level, it would be safe to enqueue the subsequent packets into the lower level without causing packet misordering. At this point, 'Step-down FIFO' serves as a special FIFO at a higher level that provides the same granularity of a lower level. A 'Step-down FIFO' expands a FIFO at the higher level into multiple queues with finer granularity, preserving the departure

Figure 16: Step-down FIFO

time difference between the packets. When a flow's latest packet enqueues into a 'Step-down FIFO' at level l, Gearbox schedules it with the granularity of level $(l-1)$. Thus, we can mark the 'Last packet enqueued level' $L_i = (l-1)$. As a result, we can enqueue the subsequent packets from the same flow into level $(l-1)$.

Figure 16 illustrates how a 'Step-down FIFO' works. FIFOs marked in yellow at level 2 and 3 are 'Step-down FIFOs', which maintain the same granularity as the next lower level. In this example, Gearbox uses 10 FIFOs to achieve a Step-down FIFO with the finer granularity. Packets $A1$ and $A2$ enqueue the 'Step-down FIFO' and preserve their departure times $F_{(A,1)} = 10$ and $F_{(A,2)} = 11$ with the granularity of $g_1 = 1$. By doing so, Gearbox will schedule packets $A1$ and $A2$ with the same granularity at level 1 and the packets will leave the scheduler at $t_s = 10$ and 11. In this case, it is safe to place packet $A3$ at level 1 without causing packet out-of-order issues. In this example, 'Step-down FIFO' makes it possible for flow A to step down from level 2 to level 1.

With a 'Step-down-FIFO', the flows that follow their allocated rate will eventually get back to the level they belong to and restore their DTD. Assume flow i belongs to level l, where the departure time of its packets increases by g_l. Due to prior burstiness, packets from flow i queue up at a higher level l' and need to step back down to level l. Since flow i now follows its admitted rate r_i, its packets arrive with a departure time interval of g_l without accumulation. Based on the basic idea of Gearbox in Section 3.1, each FIFO at level l' (including the 'Step-down FIFO') covers a departure time range of $g_{l'}$ and $g_{l'} >> g_l$. Since $F_{(i,k)}$ increases by g_l, eventually there will always be a packet that enqueues in the 'Step-down FIFO' at level l'. As the 'Step-down FIFO' at level l' schedules packets with the granularity of g_l, Gearbox will mark the last enqueue level of flow i as $L_i = l$ and the subsequent packets from flow i will get back to level l. In this way, the Step-down-FIFO enables the flows that follow their allocated rates to eventually get back to the lower level to which they belong.
Figure 17: Gearbox's Application in a NIC (egress only shown)
Figure 18: Gearbox's Application in Multi-pipeline Systems

B   Gearbox's Application in NIC and Multi-pipeline Systems

Figure 17 shows a Gearbox application in a NIC with only the egress path shown. Packets from the server arrive over PCIe and are stored in the Packet Buffer. The packet headers are parsed and classified in the Parser & Classifier block to extract the flow id and the packet length. The Departure Time Calculator computes the departure time using the packet length and forwards it to Gearbox for enqueue. Gearbox dequeues descriptors and forwards the packet pointers to the Packet Buffer to output the packets.

Figure 18 shows a Gearbox application in a multi-pipeline switch. After the parsing stage, the classification (flow identification) is done in the first stage. The second stage computes the departure times, which are fed to multiple Gearboxes for enqueue. Dequeued packets are output by the deparser.

Performance Interfaces for Network Functions

Rishabh Iyer, Katerina Argyraki, George Candea

EPFL, Switzerland

Abstract

Modern programmers routinely use third-party code, and infrastructure operators deploy software they did not write. This would not be possible without semantic interfaces—documentation, header files, specifications—that succinctly describe what that third-party code does.

We propose *performance interfaces* as a way to describe a system's performance, akin to how a semantic interface describes its functionality. We concretize this idea in the domain of network functions (NFs) and present a tool (PIX) that automatically extracts performance interfaces from NF implementations. We evaluate PIX on 12 NFs, including several used in production. The resulting performance interfaces are accurate yet orders of magnitude simpler than the code itself and take minutes to extract. We show how developers and operators can use performance interfaces to identify performance regressions, diagnose and fix performance bugs and identify the latency impact of NIC offloads.

PIX is available at https://github.com/dslab-epfl/pix.

1 Introduction

Semantic interfaces (e.g., abstract classes, specifications, header files, documentation) succinctly describe a program's externally visible functional behavior, enabling engineers to use the system productively. This makes it possible for programmers to use a lot of third-party code and makes infrastructure operators comfortable with deploying software they did not write.

We do not know of an equivalent construct for describing performance behavior in a way that is simultaneously succinct, precise, complete, and human-readable. Engineers reason about performance in terms of envelopes (e.g., "runs in $O(n)$ time") and benchmarks, which implies that they deploy their system without understanding the entire spectrum of performance it can exhibit. As a result, untested inputs can exercise mysterious code paths that lead to unexpected performance behavior [4, 36, 39] and a perpetual need to fix performance bugs [35, 43].

In this paper, we explore the idea of a *performance interface*: a description of a system's performance behavior that is simultaneously succinct, precise, and human-readable. What should such an interface look like? Like a good semantic interface, it should be "much smaller and simpler than the code" [48], so it must abstract away certain details—but which ones? Performance problems often lie in low-level implementation details as well as the code's interaction with the environment (e.g., specifics of the underlying hardware's cache hierarchy). Is it possible to capture all the relevant performance behaviors of a system while being "much smaller and simpler" than the system itself?

We propose that the performance interface of a system be a *program* that accepts the same inputs as the system and outputs how long the system would take to process the given input[1]. A performance interface has a *resolution*, which quantifies the smallest change in performance that it specifies (e.g., 50 ns, 1 mem-op)—the coarser the resolution, the simpler the interface. We distinguish a *deployment-specific* interface from a *general-case* one: The former is much simpler and of greater interest to an operator, who wants to understand the system's performance behavior in her specific environment, while the latter is most useful to developers. This distinction, along with resolution, makes it possible to have performance interfaces that capture only those behaviors that are relevant to the case at hand. In other words, the two concepts enable abstraction of performance behavior.

We concretize our proposal in the context of network functions (NFs), i.e., load balancers, firewalls, NATs, etc. NFs are typically on the critical path of serving a user request and often face unpredictable traffic coming from the outside world. For instance, any packet that enters a service provider's data center traverses at least one load balancer/reverse proxy and typically also a firewall—the latency that each NF adds to the packet directly impacts the user-perceived latency. A recent survey [54] of network operators found NF performance degradation to be a frequent pain point, and such performance bugs to be among the hardest to diagnose.

To make NF performance interfaces useful today, we developed PIX (**P**erformance **I**nterface e**X**tractor). PIX takes as input NF code written in C and outputs general-case performance interfaces in the form of small Python programs that it can then specialize into deployment-specific interfaces for individual deployments. PIX currently supports three latency-related metrics: number of instructions, number of memory operations, and number of CPU cycles. For each metric, PIX outputs one set of Python programs; each set contains one Python program per relevant range of resolutions. All PIX-extracted performance interfaces are specific to the CPU's ISA.

---

[1] In this paper we focus on system latency, not throughput.

Further, the interfaces for CPU cycles are specific to the micro-architecture of the underlying hardware and assume that the NF does not contend for hardware resources with other processes (i.e., assume either smart process co-location [12, 31, 52] or process isolation, using techniques such as cache partitioning [77]). Under the covers, PIX employs symbolic program analysis techniques to reason about the NF's performance behaviors.

We evaluate PIX on 12 open-source NFs, including the Katran load balancer [71] used at Facebook, the Natasha NAT [58] used at Scaleway and the XDP packet filter from the Cilium project [14]. All 12 NFs were written using either the Linux kernel's eBPF XDP [82] framework or the DPDK [21] kernel-bypass framework, two of the most popular ways to develop high-performance NFs. Our evaluation shows that the extracted performance interfaces are accurate yet orders of magnitude simpler than the code, and take minutes to obtain. We show how performance interfaces extracted by PIX can be used to identify performance regressions, diagnose and fix performance bugs, and identify the latency impact of NIC offloads.

In summary, we make two contributions in this paper:

- We propose the concept of performance interfaces, which leverages the notions of performance resolution and deployment-specific interfaces to enable abstraction of performance behavior.
- We demonstrate that it is feasible to build a tool that automatically extracts performance interfaces from NF code, and that these interfaces can be accurate-yet-simple enough to help understand and debug performance.

In the rest of the paper, we describe how we think a performance interface should look like (§2). Then, we describe PIX (§3) and use it to evaluate the feasibility and utility of performance interfaces for NFs (§4). Finally, we discuss how PIX can generalize to systems beyond NFs (§5), related work (§6), and conclude (§7).

2 Performance Interfaces

In this section, we present our proposal for performance interfaces, and describe how we envision them being used.

Target audience: We target two categories of audience for any system: The *developers* write the code for the system and are familiar with its low-level implementation details, but not necessarily with all possible performance behaviors it can exhibit. The *operators* did not write the code but instead seek to use/deploy/build on top of the system in their respective environments. They

are unfamiliar with and do not necessarily want to understand its low-level details. Further, unlike the developers who care about the system's performance in all settings, they care primarily about its performance in their specific use-case/deployment. These categories can vary from system to system—the developer of an application A might themselves be building upon on a network stack B, making them an operator for that stack.

Design goals: We envision that a "performance interface" must describe the system's externally visible *performance* behaviors, just as a semantic interface describes a system's externally visible functionality [48].

The primary challenge in summarizing performance is that systems typically expose a greater variety of performance behaviors than semantic ones. Hence, a performance interface that perfectly predicts every possible performance behavior would likely be so complex that it wouldn't deserve to be called an interface.

We look for a compromise, i.e., a way to summarize performance that achieves a good balance between the following properties: (1) **Accuracy**, i.e., the ability to summarize performance completely (for every possible input) and precisely (with a small error). (2) Simplicity, i.e., being **smaller** than the code and as **abstract** as possible—summarize performance in terms of primitives appropriate for a semantic interface of the system, and reveal implementation details only when necessary.

We also aim for (3) **Portability**. A system's performance may depend significantly on its environment (e.g., workload, hardware). For instance, adversarial traffic causing L3 cache misses can degrade NF latency by $3\times$ [64]. The interface should make it easy to quantify the impact of a particular environment on performance, enabling porting of the interface across deployments.

State of the art: Today, performance is typically summarized through upper bounds—Big-Oh notation or worst-case execution time [79]—and statistics (e.g., x-th percentile latency). These descriptions maximize simplicity at the cost of accuracy—there are many inputs for which they do not provide accurate predictions.

We draw inspiration from two recent proposals that describe a system's performance behavior as performance annotations [69] and performance contracts [41] respectively. Freud [69] describes a method's performance as a performance annotation: a set of ⟨input/global-variable constraints, performance formula⟩ tuples, and each formula is a mathematical function of the method's input and/or global variables. Bolt [41] describes an NF's latency as a "performance contract:" a set of ⟨input constraints, performance formula⟩ tuples, where each formula is a function of the system input and "Performance-Critical Variables" (PCVs).

Since we reuse the idea of PCVs from performance contracts [41], we elaborate upon them here. A PCV is a parameter that captures the influence on performance of all factors other than the input packet (e.g., NF configuration, state built up by prior packets, hardware characteristics, etc). A PCV is not always an explicit variable in the NF implementation, rather it can be an implicit "ghost" variable [29, 32]. For instance, if an NF employs a hash table, a PCV could be the "number of collisions" encountered by the current packet—this ghost variable allows latency to be expressed as a function of, among other things, the number of collisions. Independent prior work [37, 38] on symbolic bounds has also argued for the use of a PCV-like abstraction to succinctly summarize the performance behavior of stateful programs.

However, neither annotations nor contracts were designed to be "performance interfaces". Contracts sacrifice simplicity for accuracy—they include a list of input constraints, which can be as many as the number of execution paths through the system and reveal low-level implementation details *even when unnecessary*. Annotations do not meet our accuracy goal as they do not capture how performance depends on state built from past inputs, e.g., the contents of a hash table or a hardware cache (Appendix A).

Definition: The *performance interface* of a program P with procedures $p_1, p_2, ...$ is a program $S_P = \{p'_1, p'_2, ...\}$. A procedure $p'_i \in S_P$ takes the same inputs as the corresponding $p_i \in P$ and returns the performance of executing p_i. This return value corresponds to a performance metric (e.g., # of `x86` instructions, # of CPU cycles). The *resolution r* of S_P is the smallest difference in performance that S_P can specify: if $\mathcal{P}(p_i(I))$ is p_i's performance given input I, then $|p'_i(I) - \mathcal{P}(p_i(I))| < r, \quad \forall p_i, I$.

A performance interface can be for the "general case" or specific to a deployment.

In a *general-case performance interface*, the procedures p'_i compute performance as a function of PCVs [41]. PCVs ensure that the interface can describe the performance of each p'_i in full generality, i.e., for arbitrary workloads and hardware configurations.

A *deployment-specific performance interface* is simpler than the general-case one and does not contain PCVs. Instead, procedure p'_i returns performance as a statistic (e.g., median, max, 99th percentile), computed for a given joint probability distribution of the PCVs that describes P's environment for a particular deployment. In this work, an NF's deployment environment is defined by its configuration read at startup, a representative workload, and the specific hardware it runs on.

Example: We illustrate with an example implementation of a MAC learning bridge (Fig. 1) that uses a

```
void bridge(pkt* p, time_t now) {
  expire_stale_ports(now);
  if (invalid_hdr(p)) {
    DROP(p);
    return;
  }
  /* Learning source MAC addr */
  if(!slow_MACtable_get(p->src_mac, &p->port))
    slow_MACtable_put(p->src_mac,&p->port);
  else
    slow_MACtable_update(p->src_mac, now);
  /* Forwarding based on dest MAC addr */
  if (fast_MACtable_get(p->dst_mac,&out_port))
    FORWARD(p,out_port);
  else if (slow_MACtable_get(p->dst_mac,&
    out_port))
    FORWARD(p,out_port);
  else
    BROADCAST(p,p->port);
}
```

Figure 1. Example implementation of a MAC learning bridge

fast MAC table, implemented in hardware, and a slow software-based table, based on a cuckoo hash table. Table 1 shows the performance cost of this implementation's procedures in terms of executed lines of pseudocode (LOP), a performance metric we use for illustration only. For now, we assume these costs, we elaborate on how they are obtained in §3.

Operation	Performance [LOP]
`expire_stale_ports()`	$40 + 60 \times$ n_stale
`invalid_hdr()`	5
`DROP`	1
`FORWARD`	60
`BROADCAST`	200
`fast_MACtable_get()`	10
`slow_MACtable_get()`	50
`slow_MACtable_update()`	70
`expire_stale_ports()`	$40 + 60 \times$ n_stale
`slow_MACtable_put()`	$110 + 80 \times$ n_evicted $+ 120 \times$ occ $\times$ rehashing

Table 1. General-case performance of procedures called by the code in Fig. 1. Two have non-constant performance: expiring learned ports is linear in the number of stale ports, and doing a `put()` in the cuckoo hash table depends on the number of keys that must be evicted and whether rehashing is necessary.

Fig. 2 shows two performance interfaces of this implementation. Since it exposes a single procedure, the performance interface also has a single procedure. The resolution of the performance interfaces is $r = 50$ LOP.

The general-case interface gives performance as a function of 4 PCVs: number of stale flows (`n_stale`), hash-table occupancy (`occ`), number of hash-table evictions triggered by this input (`n_evictions`), and whether rehashing is needed (`rehashing=1` if yes, 0 otherwise). Since the performance metric LOP is independent of the underlying hardware, all 4 PCVs are specific to the

```python
def perf_bridge_gc(p,now):
  # Metric: LOP, Resolution: 50
  # NF state: slow_MACtable, fast_MACtable

  if invalid_hdr(p):
    return 46 + 60* n_stale
  if fast_MACtable_get(p->dst_mac) or
    slow_MACtable_get(p->dst_mac):
    return 280 + 60* n_stale + 80*
    n_evictions + (120* occ) * rehashing
  else
    return 445 + 60* n_stale + 80*
    n_evictions + (120* occ) * rehashing
```

```python
def perf_bridge_ds(p,now):
  # Metric: LOP, Resolution: 50
  # Statistic: 50th percentile
  # NF state: slow_MACtable, fast_MACtable

  if invalid_hdr(p):
    return 106 #(46+60)
  if fast_MACtable_get(p->dst_mac) or
    slow_MACtable_get(p->dst_mac):
    return 340 #(280+60)
  else
    return 505 #(445+60)
```

Figure 2. General-case (left) and deployment-specific (right) performance interfaces for the bridge (Fig. 1). Each return value in the latter is the median LOP executed for the assumed PCV distribution.

bridge's implementation. If the bridge stored the MAC table using a binary tree instead of a cuckoo hash table, the interface would describe performance using different PCVs (`tree_depth` instead of `rehashing`).

The deployment-specific interface gives the median latency for a deployment where the expected workload is such that 50% of input packets encounter no hash collisions and expire ≤ 1 stale ports. The interface produces concrete numbers corresponding to this deployment-specific PCV distribution. Note, the deployment-specific interface does not restrict the inputs (e.g., the types of packets), it only instantiates the PCVs.

This performance interface captures all the performance behaviors of the bridge that are externally visible at resolution $r=50$. It is accurate, in that it correctly predicts performance (at the given resolution) for every possible input. It is smaller and simpler than the implementation: each procedure considers only three operations (invalid header check, fast table lookup, and slow table lookup), since these are the only ones that affect performance at $r=50$. Unlike the general-case interface, the deployment-specific interface makes assumptions about the expected workload.

Why represent the interface as a Python program?
We believe that an interface that presents performance like the system itself—through code that branches on the input—is more intuitive than a list of input constraints for developers and operators. We chose Python due to its ubiquitous use [33].

Resolution: Often, developers and operators do not care about certain performance differences, either because they do not affect their performance targets, or because they are masked by the environment. For example, developers building minute-scale applications may not care about μs-scale variability in the networking stack, while those building μs-scale ones typically do.

The notion of resolution enables the developer/operator reading the interface to choose between multiple levels of abstraction (trading off accuracy for simplicity) in a controlled manner. A performance interface at a specified resolution only differentiates between input classes whose performance differs by more than the resolution—implementation details that cause variability relevant to the specific developer/operator are abstracted away. In our bridge example, a performance interface with a resolution of 1 LOP must report the performance of each forwarding behavior separately; an interface with resolution $>= 45$ LOP can abstract away the difference between a fast and slow lookup, and an interface with resolution $>= 115$ LOP can abstract away the difference between a successful and unsuccessful lookup.

Picking the right resolution: We envision developers/operators picking their respective resolutions based on the performance variability they are willing to tolerate in their deployment scenarios. In §3, we show how PIX goes a step further for those unsure of the "right" resolution, by identifying a minimal set of resolution thresholds that yield all the possible different performance interfaces. This is possible since the performance interface can only elide each implementation detail at a distinct resolution threshold, which results in it not changing between two such thresholds. In our bridge example, {1, 20, 45, 115, 210} is such a minimal set of resolution thresholds, i.e., other resolutions don't yield different interfaces (e.g., the interface at $r = 50$ is identical to that at $r = 46$). By identifying these resolution thresholds, PIX enables developers and operators to easily pick the resolution (and corresponding interface) that achieves the desired trade-off between accuracy and simplicity.

Deployment-specific interfaces: We chose to have separate general-case and deployment-specific interfaces to

provide a different balance between accuracy and simplicity for operators and developers respectively.

General-case interfaces are meant for developers. Developers cannot always predict where/how their code will be deployed, and are hence often interested in the performance of their system when deployed in arbitrary environments. The general-case interface provides them with such a description by summarizing the impact of the environment on the system's performance using PCVs. While PCVs do reveal implementation details (e.g., n_evicted, rehashing reveal the use of a cuckoo-hash table), these details *are necessary* to summarize performance *for an arbitrary workload*, so they must be represented in the general-case interface.

We designed the deployment-specific interface for operators. Since operators are unfamiliar with the system's implementation and only care about the system's performance behavior in their particular deployment environment, the deployment-specific interface does away with the hard-to-understand PCVs by instantiating them with a distribution specific to that deployment. This enables the deployment-specific interface to summarize performance in an NF-generic way—any NF would normally involve a header check and state lookups—and be understood by almost any NF operator. Of course, it does reveal one important aspect of the implementation, namely the distinct fast and slow tables. However, this aspect (which would have no place in a semantic interface) is crucial to any bridge operator interested in performance.

That said, we do not envision the separation between the general-case and the deployment-specific interfaces being set in stone—developers may refer to the deployment-specific interface to understand performance in the face of specific workloads, while operators may refer to the general-case interface to understand performance beyond their expected workload.

3 Extracting Performance Interfaces

We now describe PIX, which takes as input an NF implemented in C and automatically extracts performance interfaces in the form of Python programs.

We designed PIX to meet two goals: (1) *miniminal developer effort*: developers/operators should not need to write performance test suites or proof lemmas, and (2) *allow for proprietary NFs*: NF vendors typically provide operators with only binaries [55]; it's ok for them to provide a performance interface, but not source code.

Fig. 3 presents an overview of PIX. The NF developer gives the PIX back-end the NF source, augmented with a few single-line annotations akin to instantiating a type in a higher-level language. PIX combines this with a preanalysis of the data structures used by the NF and extracts the general-case interfaces for all meaningful resolution

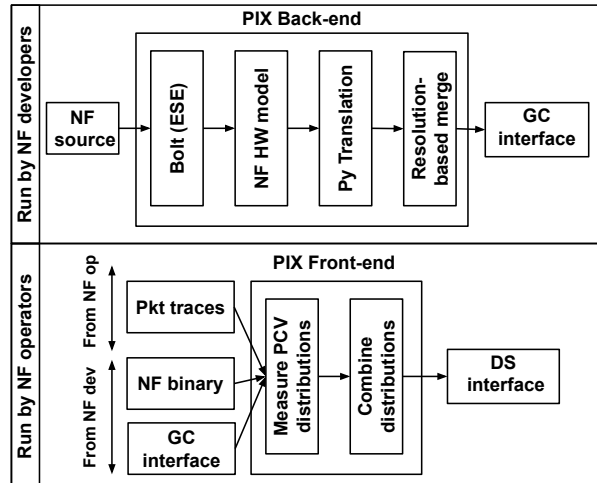

Figure 3. Overview of PIX. GC and DS refer to general-case and deployment-specific respectively.

ranges. The NF operator provides the PIX front-end with an NF binary and general-case interface (provided by the NF developer), along with a (set of) packet trace(s) that represent the expected workload in their deployment. From these, PIX extracts the deployment-specific interfaces for all meaningful resolution ranges. NF developers/operators can also query PIX with a specific resolution, to get the interface at that resolution.

Limitations and Assumptions: The PIX back-end uses exhaustive symbolic execution (ESE) [45] to automatically analyze the NF code. For this to work, the NF needs to be single-threaded, all its loops except the top-level event loop must have statically computable bounds, and it must keep all history-dependent state in data structures with clear interfaces. PIX cannot extract performance interfaces for NFs that do not meet these requirements.

Many (not all) data-plane NFs meet these requirements. For instance, many NFs are written using the eBPF [82] framework as stateless modules that keep their state in cleanly separated, kernel-maintained eBPF maps [24]. Other examples include recently proposed NF frameworks that build upon the DPDK kernel-bypass framework [21] like FastClick [5] and Vigor [83], which impose the use of a specific set of well-separated data structures to store NF state. Counterexamples include Intrusion Detection Systems (IDSes) and TCP-terminating NFs; in general PIX cannot extract interfaces for them and we describe this limitation in more detail in §5.

PIX-extracted interfaces only summarize the processing latency for each packet and do not reason about queuing latencies. Reasoning about these latencies would require PIX to reason about multiple inputs together, and for this, we need to employ techniques more sophisticated than ESE [83]. Reasoning only about processing

latency allows PIX to avoid reasoning about load-based variability since processing latency (unlike queueing latency) does not vary with load.

To capture how hardware affects performance with reasonable accuracy, PIX assumes that the NF runs pinned to a core and does not significantly contend for hardware resources, e.g., due to smart process isolation [12, 31, 52, 77]. We believe network operators keen on predictable performance are likely to employ such techniques.

Implementation: PIX builds on the KLEE symbolic execution engine [9]. We extended KLEE with 4629 lines of C++ code to implement the first two steps of the back-end. We synthesize the Python-based interfaces using 1825 lines of OCaml. We implemented resolution-based merging and the PIX front-end in 1221 lines of Python.

3.1 Extracting general-case interfaces

We now describe how the PIX back-end extracts general-case interfaces from NF source code.

Step 0: Pre-processing: This step outputs the performance of each execution path of the NF in terms of hardware-independent metrics as a function of PCVs specific to the NF's implementation (we refer to these PCVs as *hardware-independent PCVs* henceforth). PIX currently supports two hardware-independent metrics—instruction count and memory-access count. We call this Step 0 because it is not part of our contribution, we largely reuse the approach and tool from Bolt [41].

Bolt relies on the observation that data-plane NFs tend to use the same, relatively few data structures, mainly hash tables/maps and buffers/rings. One can therefore collect these data structures in a library, have an expert "pre-analyze" them once, and then amortize this analysis cost across all NFs that use the library. Bolt's pre-analysis consists of two manual tasks for each call in the library's interface: (1) identify the PCVs relevant to that call, and (2) write a simple symbolic model of the call. Such manual effort is reasonable because it is a rare effort (e.g., once per update to the Linux kernel's eBPF maps) and it is done by the maintainer of the data structure library instead of its users. To illustrate, there were 34 new commits in Linux's eBPF maps last year [23] while the Cilium project [14] alone—just one among hundreds of projects that leverage eBPF maps—had an order of magnitude more commits during that same period [13]. Further, independent prior work [38] has observed that most data structures require only a "few" PCVs, and identifying them is "straightforward". Our experience as the "experts" for this work corroborated this observation—identifying PCVs required only single-line loop annotations which took ≤ 1 person-hour for someone familiar with the data structure code.

The Bolt tool takes as input the NF source code, as well as the symbolic models and loop annotations for the state-accessing calls made by the NF; and outputs the performance of each execution path through the NF as a function of the hardware-independent PCVs.

In Step 0, PIX uses the Bolt tool as stated above, and also automatically instruments the NF code such that it can log the values of the hardware-independent PCVs for each input packet encountered.

Step 1: NF-domain hardware model: This step characterizes the performance of each execution path of the NF in terms of hardware-dependent metrics (CPU cycles), by introducing hardware-dependent PCVs; i.e., PCVs that capture the interaction between NF and hardware.

PIX uses the notion of a CPI (Cycles Per Instruction) stack [27] to compute the number of CPU cycles of an execution path. A CPI stack breaks down the average CPI for a program executing on a given microprocessor into a base CPI plus various CPI components that reflect "lost" cycle opportunities due to miss events such as branch mispredictions and cache/TLB misses. In general, replicating a perfect CPI stack is infeasible—it is equivalent to analyzing each execution path to the depth provided by a cycle-accurate simulator.

We leverage NF-domain knowledge to eliminate CPI components and pick only the necessary set of hardware-dependent PCVs. When an NF runs pinned to a core and with limited contention for hardware resources, the dominant hardware factor that influences its performance is the last-level cache (LLC) [20, 52, 77]. Hence, PIX introduces only two hardware-dependent PCVs—*base_CPI* and *LLC_miss_latency*—and expresses a path's CPU cycle count as *instructions · base_CPI + LLC_misses · LLC_miss_latency*. Note, while PIX uses the same two PCVs for all NFs, the values of these PCVs vary with each *<NF, HW>* pair (§3.2). To track possible LLC misses, PIX leverages taint-analysis [70] to identify independent heap accesses specific to the current input; it then branches on each such access, with one outcome being an LLC miss and the other an LLC hit.

Step 2: Python program: The previous steps specify an NF execution path as a set of symbolic constraints on the input packet and symbols arising from calls to data structures; this step translates these constraints into human-readable python code and outputs a general-case performance interface of the NF with a resolution of 1.

PIX translates symbolic constraints on the input packet using knowledge of the header format of the popular networking protocols (e.g., IPv4, TCP, QUIC). For instance, the constraint $pkt[23 : 24] == 6$ on a non-tunnelled IPv4 packet is translated to $pkt.isTCP$.

```
1 # Developer annotation:
2 DS_INIT(&map,"macTable","ethaddr", struct
      eth_addr,"port", int);
3
4 # Starting condition derived from implem:
5 if bpf_map.unnamed_symbol
6 # Transform based on called library function
7 if bpf_map.contains(pkt[7:12])
8 # Transform based on developer annotation
9 if macTable.contains(pkt.src_mac)
```

Figure 4. Example of PIX's constraint rewriting.

PIX translates symbols arising from calls to data structures using call context and developer-provided annotations (one annotation per instantiated data structure). Fig. 4 illustrates such a translation: Line 2 shows a developer's annotation for a data structure of type `map`: it indicates that this NF uses this map as a `"macTable"`, which maps `"ethaddr"` keys to `"port"` values; these are human-friendly terms chosen by the developer to help the generation of simple performance interfaces. Line 5 shows a constraint derived from the NF code that concerns this map. Line 7 shows how PIX rewrites this constraint because it knows that this is a call to `bpf_map_-lookup_elem()` with an argument corresponding to bytes $7 - 11$ of the input packet. Line 9 shows how PIX further rewrites the constraint because the developer's annotation enables PIX to identify the given bytes as the input packet's source MAC address.

The annotation on Line 2 is the only annotation that the NF developer needs to provide. We believe such one-line annotations are reasonable since they are similar to instantiating a type in a higher-level language.

Step 3: Resolution-based merging: This step uses the notion of resolution to simplify the performance interface: First, it calculates the maximum performance impact of each constraint, i.e., the maximum performance difference between two execution paths that only differ w.r.t this constraint. The set of distinct "maximum performance impacts" forms the minimal set of resolution thresholds. Second, it eliminates all constraints with an impact smaller than the target resolution.

3.2 Extracting deployment-specific interfaces

To extract a deployment-specific interface, the PIX frontend takes as input the NF binary and its general-case interface[2], provided by the NF developer/vendor; along with a (set of) deployment-specific packet trace(s), provided by the NF operator. It then runs the NF binary using the packet trace(s) as input, infers the deployment's PCV

distributions, and instantiates the deployment-specific interface. Running the NF allows PIX to extract accurate deployment-specific interfaces since it can precisely measure the performance impact of the NF's environment as opposed to modeling it.

PIX infers three PCV distributions per NF, deployment:

Hardware-independent PCVs: PIX leverages the instrumentation introduced in Step 0 to measure the values of these PCVs encountered by each packet in the provided trace(s). It then computes a joint probability distribution of these PCVs, since they tend to be highly correlated (e.g., in Table 1, `n_stale` and `n_evictions` are both functions of `occ`).

Base CPI: PIX measures this using hardware performance counters [75] available on all major processors today. Since the packet trace(s) may not exercise all execution paths, PIX assumes the same base-CPI distribution across all paths, and it provides warnings if it detects significant differences (e.g, some paths use expensive x86 instructions, like integer divide, while others don't). We think this is a reasonable assumption because the base CPI is only a function of the instruction mix (it does not include any miss events). In §4.1, we experimentally validate this.

LLC miss latency: Measuring the distribution of LLC miss latency ideally requires sophisticated NF-specific testing [64], to account for the NF's particular instruction- and memory-level parallelism. PIX avoids this because it targets NFs that keep all their state in a relatively small set of pre-analyzed data structures. For each data structure, we craft a microbenchmark that triggers LLC misses.[3] PIX estimates the LLC-miss-latency distribution of each data-structure call in a given deployment, by running the corresponding microbenchmark on the deployment's hardware. In §4.1, we experimentally show that our approximation, performs well in practice (avg. error of < 10%). Note, our approximation concerns the *latency* introduced by LLC misses, *not the number* of LLC misses—the PIX back-end tracks LLC misses per path in Step 1.

Finally, PIX instantiates each formula in the general-case interface with these inferred distributions to compute the requested latency statistic (e.g., 50th percentile in Fig. 2). We show examples of deployment-specific interfaces and their distributions in §4.

---

[2]The operator cannot be certain that this general-case interface is accurate for the production binary, but we do not see this as a barrier to adoption: operators routinely deploy NF binaries while relying only on non-attested configuration interfaces and vendor manuals [55].

---

[3]The expert must do this once per data structure, like the pre-analysis.

Framework	NF	Functionality
eBPF XDP	Katran LB	Per-flow state, per-VIP state, consistent hashing, IPv6, ICMP, QUIC, tunneling
	Cilium filter	Longest prefix matching, IPV6
	CRAB LB	Read-only state
	hXDP firewall	Per-flow state
DPDK	Natasha NAT	Per-flow state, handles fragmentation, UDPLite, ICMP, ARP
	Maglev LB	Per-flow state, consistent hashing
	VigNAT	Per-flow state, header rewriting
	Bridge	Packet duplication
	Router	Longest prefix matching
	Policer	Per-flow state, fine-grained timing
	DPDK NAT	Per-flow state, header rewriting, cksum offload
	DPDK firewall	Per-flow state

Table 2. Network functions used to evaluate PIX.

4 Evaluation

In this section, we address two main questions: (1) does PIX extract good performance interfaces, and (2) can performance interfaces make NF developers and NF operators more productive? To answer the former, we quantitatively evaluate the complexity of PIX-extracted interfaces, their accuracy, and the time it takes to obtain them (§4.1). We find that they are one to two orders of magnitude simpler and more accurate than prior work. To answer the latter question, we show how developers can use PIX-extracted interfaces to catch performance regressions and fix performance bugs (§4.2). We then show how operators can use interfaces to pick the NF variant best suited for their target hardware and to perform root-cause diagnosis of performance anomalies (§4.3).

We evaluate PIX on 12 dataplane NFs that cover a wide variety of functionality and network protocols (Table 2). These include the Katran load balancer used in production at Facebook [71], the Natasha NAT used in production at Scaleway [58], the XDP packet filter from the Cilium project [14] and an implementation of Google's Maglev load balancing algorithm [25]. The NFs were written using DPDK [21] and eBPF XDP [82], arguably the two most popular frameworks today for building high-performance software NFs. VigNAT, Policer, Router and Bridge come from the Vigor project [83], the CRAB load balancer from [46], and the hXDP firewall from [8]. The Vigor and eBPF NFs are written in the commonly used stateless/stateful split model, which makes them amenable to exhaustive symbolic execution. We modified Natasha and DPDK NAT to also have such a clean split; this took ~3 person-days per NF.

The performance metrics we use for DPDK-based NFs are `x86` instruction count, `x86` memory access count, and `x86` CPU cycles (thus wall-clock time). Note, PIX is not specific to x86 and can just as easily predict the corresponding metrics for another ISA (e.g., ARM) if the PIX front-end is given the corresponding binary. For eBPF NFs, we only analyze the NF itself, and not the eBPF maps that are part of Linux, so we only report hardware-independent metrics.

NF	Implementation		HW-independent interface (PIX)		HW dependent interface (PIX)		Bolt contract	
	LOC	CC	LOC	CC	LOC	CC	LOC	CC
Natasha	2932	192	1.8%	8.9%	2.8%	15.1%	17.4%	97.3%
Maglev	3168	29	0.9%	37.9%	1.6%	65.5%	2.1%	82.7%
VigNAT	2770	22	0.7%	36.3%	0.9%	52%	1.8%	81%
Bridge	2837	219	0.5%	2.7%	2.1%	10.5%	22.7%	98.6%
Router	1260	17	0.4%	17.6%	1.0%	29.4%	3.0%	82.3%
Policer	2466	16	0.4%	31.2%	0.6%	37.5%	1.4%	81.2%
DPDK FW	2508	21	0.8%	38%	1.0%	45%	2.0%	85.7%
DPDK NAT	1780	35	0.6%	27%	0.9%	39%	4.5%	80%
Katran	2661	3226	2.8%	0.8%	-	-	363%	100%
Cilium filter	784	42	3.2%	14.3%	-	-	10.7%	100%
CRAB	437	4	2.0%	100%	-	-	2%	100%
hXDP FW	312	33	3.8%	15.1%	-	-	30%	100%

Table 3. Complexity of extracted interfaces and Bolt contracts vs NF implementation. "($x\%$)" means "x of implementation". For each NF, the complexity is calculated for an interface with resolution equal to 10% of the maximum latency variability the NF can exhibit. Since Bolt computes the worst-case performance for HW-dependent metrics (not shown), the numbers are identical to those for HW-independent metrics.

Our testbed consists of two directly connected servers: a device under test (DUT) and a traffic generator and sink (TG). The servers are identical, with an Intel Xeon E5-2667 v2 processor @ 3.30 GHz, 32 GB of DRAM, and Intel 82599ES 10-Gbps NICs. The DUT runs one of the NFs and measures the performance, while the TG uses MoonGen [26] to generate traffic.

4.1 Does PIX Work?

In this section, we show that extracted interfaces are $1-2$ orders of magnitude simpler than both the NF implementations and the equivalent Bolt contracts (§4.1.1). Their accuracy is 100% for reasonable resolutions, while at the finest resolution they are still practical and considerably better than Bolt, the state of the art (§4.1.2). Extracting a performance interface typically takes minutes (§4.1.3).

4.1.1 Are performance interfaces user-friendly?

To evaluate the "human palatability" of the performance interfaces, we (1) measure their complexity in terms of both lines of code (LOC) and cyclomatic complexity (CC) [78], and (2) evaluate whether the primitives exposed by the performance interfaces are those that NF developers and operators are familiar with.

Table 3 compares the complexity of the PIX-extracted interfaces and the Bolt contracts, measured as a fraction of LOC and CC of the implementation. In a nutshell, the extracted interfaces have $26-210\times$ fewer LOC than the corresponding implementations and are $3-124\times$ less cyclomatically complex, ignoring CRAB, which is already simple to start with. The performance resolution allows PIX-extracted interfaces to be $2.3-129\times$ shorter than the Bolt contracts, and $2.1-124\times$ less cyclomatically complex, by abstracting away irrelevant details. The more complex an NF, the higher this reduction in complexity,

which argues for the real-world utility of performance interfaces.

Fig. 5 illustrates the impact of varying resolution on the complexity of Katran's performance interface. At the finest granularity, Katran's instruction-count interface, like the Bolt contract, is fairly complex (LOC=9675, CC=3226 independent paths). Since no two packets in Katran can incur an instruction count that differs by more than 854 instructions (number determined by PIX and verified by us), for resolutions above 854 the interface becomes a simple upper bound. In between these two extremes, we see how low-level details get abstracted away—for instance, at resolution=50 instructions, we see a 125× drop in complexity (LOC=75, CC=26). The Bolt contract, however, lacks the notion of resolution and thus remains 3.6× longer and just as cyclomatically complex as the implementation.

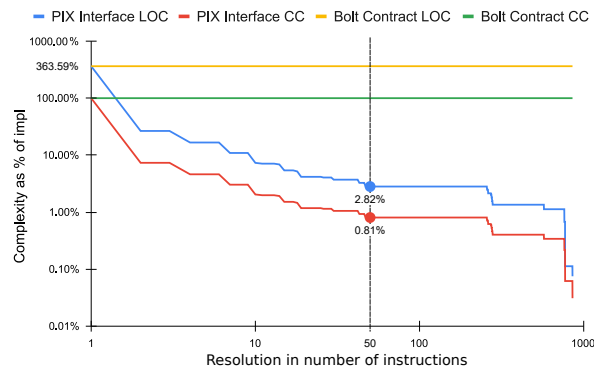

Figure 5. Impact of varying resolution on the size (LOC) and complexity (CC) of Katran's performance interface.

We conclude that PIX-extracted performance interfaces are significantly simpler than the NF implementations, which argues for them making it easier to understand performance behaviors by reading the interface than reading the code. The notion of resolution succeeds in abstracting a performance interface, giving the reader a knob with which to control the amount of detail contained in the interface.

Another aspect of palatability is how familiar the interface looks to a human reader. To illustrate this, we show an example of the general-case interface for VigNAT in Fig. 6, restricted to TCP/UDP packets for space considerations. The interface is a succinct, self-descriptive Python program. The conditions in `if` statements are expressed in terms of fields in the input packet header (e.g., `pkt.port`) or semantic operations on data structures (e.g., `nat_flowtable.contains`), which are primitives we expect both developers and operators to understand. Being a stateful NF, VigNAT's performance is influenced by NF state, and the interface reflects this via

```
def perf_vignat_gc(pkt):
  # Perf metric: x86 instructions
  # Resolution: 10
  # NF state:
  #   flowtable
  # PCVs:
  #   e - expired flows
  #   t - bucket_traversals
  #   c - hash_collisions

  x = 19*e*t + 40*e*c + 227*e + 123

  if not (pkt.is_IP) or not(pkt.is_TCP or pkt.
    is_UDP):
    return x + 7
  else:
    if pkt.port != internal_network_port:
      if flowtable.contains(pkt.flow):
        return x + 289
      else:
        return x + 68
    else:
      if flowtable.contains(pkt.flow):
        return x + 18*t + 30*c + 395
      else:
        return x + 31*t + 30*c + 547
```

Figure 6. Extracted general-case interface for VigNAT.

PCVs, documented in the header. Bolt, on the other hand, does not translate low-level details and exposes primitives such as the starting condition on line 4 of Fig. 4. While such details are understandable to the NF's developer, they make the contract hard to read for those unfamiliar with the code.

Finally, we illustrate the impact of deployment-specific instantiation of interfaces on their palatability. Fig. 7 shows the interfaces for VigNAT's 50th and 95th percentile latencies and the distribution underlying them, for a particular *<workload, HW>* pair. The deployment-specific instantiation turns each formula (expressed in terms of PCVs in the general-case interface) into concrete values specific to the environment and workload, thus tailoring the interface to an operator's needs. The latency CDF also enables interested operators to understand how VigNAT's percentile latency varies.

4.1.2 Accuracy of performance interfaces

We now evaluate the prediction error of PIX-extracted interfaces, i.e., the difference between the latency predicted by the interfaces and the measured latency.

To do so, we use PIX to extract interfaces for all 8 DPDK NFs[4] for two hardware-independent metrics (`x86` instructions and memops) and one hardware-dependent one (`x86` cycles). For each NF, we instantiate two deployment-specific interfaces corresponding to two very different deployments—typical traffic representative of university networks [6] and adversarial traffic that seeks denial-of-service [64]. The above deployments represent opposite ends of the spectrum for *absolute* NF latencies [64]— e.g., adversarial traffic incurs 2.1× greater latency than typical traffic in VigNAT. To instantiate each deployment-specific interface, we use PCAP traces of 100M packets each. These traces are similar to what an operator could

---

[4]PIX does not support HW-dependent metrics for eBPF NFs

```python
1  def perf_vignat_ds(pkt):
2    # Metric: CPU cycles, Resolution: 200
3    # Percentile: 50
4    # NF state - flowtable
5
6    if flowtable.contains(pkt.flow):
7      return 301
8    else:
9      if pkt.port != internal_network_port:
10       return 92
11     else:
12       return 558
```

```python
1  def perf_vignat_ds(pkt):
2    # Metric: CPU cycles, Resolution: 200
3    # Percentile: 95
4    # NF state - flowtable
5
6    if flowtable.contains(pkt.flow):
7      return 395
8    else:
9      if pkt.port != internal_network_port:
10       return 97
11     else:
12       return 1037
```
Figure 7. Common-case interfaces for VigNAT (50th and 95th percentile) and the latency CDF (resolution=200 cycles).

obtain with `tcpdump` on their domain gateway and are not specific to any particular NF implementation.

For ground-truth measurements, we manually generate synthetic packet traces for each *<NF, deployment>* pair akin to Scaleway's NAT test suite [57]. We playback these traces against the NF and measure the latency of each packet (the ground truth). Note, the synthetic traces are only used to measure the ground truth and not for predicting performance, thus avoiding any overfitting.

To compare to Bolt [41], the closest prior work, we use their published code [1]. We run each deployment trace through the Bolt distiller, which computes the PCVs and concretizes the performance contracts. For a comparison to Freud [69], please see Appendix A.

We present here the prediction error for the 50th percentile, 90th percentile and 99th percentile latencies (which is the point at which PIX's limitations become evident). Appendix B provides the details for the entire spectrum. We compute all prediction errors by subtracting the relevant statistic of the measured latency distribution from that of the predicted latency distribution. The results reported are at resolution 1, where PIX does the worst.

50th percentile (median) latency: Table 4 describes the maximum and average error for median latencies across all NFs for each metric and deployment regime. Note, despite the *absolute* NF latency differing widely, PIX's prediction accuracy is similar for both deployments, showing that the PIX front-end correctly instantiates each deployment-specific interface.

	Instr's error		**Memops** error		**Cycles** error	
	Typ	*Adv*	*Typ*	*Adv*	*Typ*	*Adv*
PIX	1.8% (1.5%)	1.7% (1.2%)	4% (1.6%)	3.7% (1.5%)	26% (11%)	24% (9%)
Bolt	7.5% (3.7%)	7.6% (4.0%)	7.5% (3.7%)	7.6% (4.0%)	308% (164%)	186% (103%)
PIX improvement	4.1× (2.4×)	4.4× (3.3×)	1.8× (2.3×)	2.0× (2.6×)	11.8× (14.9×)	7.7× (11.4×)

Table 4. Max (average) median latency prediction error for PIX and Bolt for typical (Typ) and adversarial (Adv) traffic.

We find that, even in the worst case for PIX (i.e., finest resolution), the error for hardware-independent metrics is ≤4%, which is small enough to make PIX practical.

At any reasonable resolution, the error vanishes and PIX becomes 100% accurate. PIX outperforms Bolt by 4.4×.

For the CPU cycles, PIX has a maximum error of 26%. This is due to the overhead of the instrumentation used to measure the CPI and LLC miss latencies. Nevertheless, PIX's accuracy is an order of magnitude better than Bolt's since PIX reasons about hardware performance as a distribution, while Bolt only models the worst case.

90th percentile latency: Table 5 describes the prediction error for 90th percentile latencies. The results are similar to those for median latency with PIX outperforming Bolt by up to an order of magnitude. This is once again due to PIX reasoning about each of the PCVs as a distribution, while Bolt only models the worst-case.

	Instr's error		**Memops** error		**Cycles** error	
	Typ	*Adv*	*Typ*	*Adv*	*Typ*	*Adv*
PIX	1.4% (0.9%)	1.2% (0.9%)	3.2% (1.4%)	2.8% (1.2%)	22% (10%)	19% (7%)
Bolt	5.9% (2.4%)	5.3% (3.1%)	6.6% (2.9%)	6.1% (3.2%)	234% (122%)	153% (94%)
PIX improvement	4.2× (2.6×)	4.4× (3.4×)	2.0× (2.1×)	2.1× (2.6×)	10.6× (12.2×)	8× (13.4×)

Table 5. Max (average) prediction error for 90th percentile latencies for typical (Typ) and adversarial (Adv) traffic.

99th percentile latency: PIX cannot accurately predict the latency at the very end of the tail (nor can Bolt). PIX's predictions have an error of ≤61% (average 22%), while Bolt's predictions have an error of ≤45% (average 14%).

It is interesting to note that PIX *underestimates* the 99th percentile latency while Bolt *overestimates* it; this contrasting behavior is due to the different hardware models underlying the two tools. PIX underestimates the 99th percentile latency since its simple hardware model (*instructions * CPI + LLC_misses * miss_latency*) is invalid at this percentile where other hardware aspects also impact latency significantly. Bolt, on the other hand, overestimates the 99th percentile latency since its hardware model is designed to estimate the absolute worst-case latency. However, PIX's simple hardware model enables it to accurately predict performance at all percentiles except the tail (details in Appendix B); a task that Bolt's worst-case-only model is incapable of.

4.1.3 Time to extract performance interfaces

Table 6 shows the time it takes PIX to extracts the general-case interfaces for all the NFs in this evaluation. We believe that these numbers make it feasible to incorporate performance interfaces extraction part of the regular NF development cycle, e.g., as part of continuous integration.

NF	Natasha	Maglev	VigNAT	Bridge	Router	Policer	DPDK FW	DPDK NAT	Katran	Cilium filter	CRAB	hXDP FW
PIX	15	5	4	17	0.73	3	4	6	32	0.43	0.15	0.23
BOLT	6	4	2	7	0.35	1.7	2	3	28	0.26	0.1	0.13

Table 6. Time, in minutes, for PIX and Bolt to extract the general-case interfaces and contracts, respectively.

The time required to obtain the deployment-specific interface is largely a function of the time required to run the provided workload. In our experiments, we ran PCAP files with 100M packets, and it took PIX <= 5 mins to generate the deployment-specific interface for a given *<workload, HW>* pair from the general-purpose interface, regardless of NF. We conclude that PIX fulfills the portability requirement (§3) well: operators can download an NF with its general-case interface, provide a PCAP file specific to their deployment, and PIX quickly produces the deployment-specific interface.

4.2 Are interfaces useful to NF developers?

In this section, we present two workflows that NF developers can use to understand (§4.2.1) and debug (§4.2.2) the performance behavior of their code.

4.2.1 Flagging performance regressions

Programmers often introduce involuntarily performance regressions. Using performance test suites to catch such regressions is not easy, because they require environment setup, are fragile, and take long to run. We show here how a developer or a tool can instead compare the performance interface before and after a commit to identify performance regressions more quickly, conveniently, and precisely than with a performance test suite.

We wrote a script that retrieves each Katran commit and uses PIX to extract the corresponding instruction-count interface, at resolution=1. For each pair of commits a and b, there is a corresponding pair of interfaces S_a and S_b. The script finds the maximum latency (in terms of LLVM instruction count) predicted by each of the two interfaces and compares the two. We report LLVM (not eBPF bytecode) instructions since PIX builds on KLEE which interprets LLVM IR. Reporting eBPF instructions would require us to build on a tool that interprets eBPF bytecode (e.g., Serval [59])—this is an engineering task

we leave to future work. We run PIX on all commits to the eBPF portion of Katran's code.

Table 7 shows the commits where a performance regression occurs. Over the past three years, the maximum latency for new flows regressed by 14.6%.

Commit ID	Perf before [LLVM instr's]	Perf after [LLVM instr's]	Performance regression [%]
Orig commit	-	1771	-
873d0501695c	1765	1896	7.42%
39e58b530a8a	1896	1914	0.95%
458aa0907b68	1914	1933	0.99%
15f81d0e7ec6	1930	1946	0.83%
74c3338c2f7e	1952	1983	1.59%
d0790d3a3823	1983	2030	2.37%
All commits	1771	2030	14.62%

Table 7. Perf regressions in Katran (handling new flows).

We imagine using this workflow as part of continuous integration (CI) to automatically identify unintended performance regressions. The CI system can present to the developer a before-and-after comparison of performance that directly highlights for which classes of inputs the regression occurs and what the magnitude of the regression is. Compared to performance tests, this workflow consumes less developer time and fewer resources and offers better completeness.

4.2.2 Fixing performance bugs

By helping developers understand the code's performance more quickly and deeply, interfaces can help fix performance bugs. We illustrate this with two examples of performance bugs in the map used by Vigor NFs [50].

The top of Fig. 8 shows a snippet of the performance interface of the `contains` operation in libVig's `map`.

```
if map.contains(key): # --- BEFORE ---
  if not(cached(key)):
    # Warning: 2*t integer divides
    return (4*t)*miss_latency + (21*t+27)*CPI
....
if map.contains(key): # --- AFTER ---
  if not(cached(key)):
    return (1*t)*miss_latency + (18*t+27)*CPI
....
```

Figure 8. Interface for `map_contains()` before and after the bug fix. `t` is the PCV for traversals in the hash ring.

The first red flag is the warning issued by PIX itself, based on tracking of expensive x86 instructions that adversely impact CPI. Looking for integer divides in the `map` code, we found that, on each traversal, it uses two costly modulo operations. To fix the issue, we replaced them with one bitwise `and`.

The second red flag is that each traversal requires 4 independent heap accesses (`4*t`). It turns out that `key` metadata is being stored in four distinct arrays of `int`

elements. Our fix was to encapsulate `key`'s metadata in a single `struct` and use a single array with elements of this `struct` type. The rest remained unchanged.

Table 8 shows the impact of our fixes, based on Vigor's benchmarks: the two fixes, together, improve NF latency by 22% on average, and throughput by 19%.

NF	Throughput [Mpps]				Latency [ns]			
	Orig	Fix 1	Fix 2	**Change**	Orig	Fix 1	Fix 2	**Change**
VigNAT	3.88	4.36	4.68	20.62%	317	276	236	25.55%
Bridge	3.05	3.59	3.62	18.69%	410	332	323	21.22%
Maglev	2.58	2.86	3.04	17.83%	482	423	391	18.88%

Table 8. Throughput and latency of three NFs using `map`, shown before/after each performance bug fix.

4.3 Are interfaces useful to NF operators?

Operators typically care about how an NF performs in their specific deployment, not in general for everyone's deployment. We show how operators can use performance interfaces to pick the NF variant best suited to their hardware (§4.3.1) and to do a root-cause diagnosis of deployment-specific performance anomalies (§4.3.2).

4.3.1 Which NF variant for my NIC?

Modern NICs provide the ability to offload specific tasks (like checksums and encryption) to specialized hardware. It is therefore useful to know which variant of an NF takes max advantage of the offloads available on a NIC.

Fig. 9 shows the interfaces for two variants of a NAT, and the interaction with checksum offload on Mellanox ConnectX-4 [15] and Intel Ixgbe [40] NICs. The formally verified VigNAT does not do any offloading, whereas DPDK NAT does. The strings in the `if` conditions on lines 3 and 6 are identical to the one used by the NIC driver to identify itself [22]. The interface also shows the difference in latency: Ixgbe requires the software to compute a pseudo-header checksum, whereas ConnectX-4 allows full offload, so it has lower latency.

Based on this performance interface, an operator can make an informed deployment decision: if using Ixgbe NICs, choosing the verified VigNAT makes sense; else, it's a trade-off to make carefully.

4.3.2 Why do I get bad performance?

NFs running in production can face workloads that trigger surprising performance degradation. To address such anomalies, operators must first diagnose the root cause, and this often takes a lot of work.

PIX helps the search for a root cause by providing a list of possible explanations for the observed performance, ranked by likelihood. Given a problematic workload and an NF (or its general-case interface), PIX instantiates the PCVs in a deployment-specific manner and then measures the distributions for each PCV and the NF

```
# Snippet from VigNAT interface
if flowtable.contains(pkt.flow):
  return  18*t + 30*c + 518  # No offload
else:
  ....
# Snippet from DPDK NAT interface
if flowtable.contains(pkt.flow):
  if(NIC_family == "net_mlx5"):
    return  18*t + 30*c + 265 + cksum_offload()
  else:
    if(NIC_family == "net_ixgbe"):
      return 18*t + 30*c + 478 + cksum_offload()
    else:
      return 18*t + 30*c + 564
else:
  ....
```

Figure 9. Interfaces for VigNAT and DPDK NAT: VigNAT does checksums in software, while DPDK NAT offloads checksums to the NIC as much as possible.

latency. It then ranks the PCVs based on the correlation between the latency distribution and that of the PCV (using least-square fit linear regression).

To illustrate this workflow, we refer to three performance bugs that span both hardware and software root causes, shown in Table 9. The first bug occurs due to the uniform random workload causing hash collisions in a widely used hash function [42] used by Bridge; typical workloads with Zipfian distributions do not suffer from hash collisions. The second bug is caused by VigNAT's batches expiry of flows, which results in a latency spike that only becomes evident for traffic with high churn. The third bug occurs when the active flowtable in Maglev overflows the last-level cache of the server; this makes the latency spike be highly dependent on LLC configuration.

Bug	Root cause	Identified as most-likely cause?
Spike in median latency of Bridge for uniform random workload	`hash-collisions`	Yes
Spike in tail latency of VigNAT due to high churn	`expired-flows (batched)`	Yes
Spike in median latency of Maglev on a particular x86 server	`active-flowtable-size`	Yes

Table 9. Performance bugs used for root-cause diagnosis.

For each bug, we generated a workload that triggers it and provided the PCAP file to PIX, along with the general-case interface of the corresponding NF. For each bug, PIX correctly reported the culprit PCV as the most likely root cause. Of course, PIX can only track bugs that arise from PCVs it accounts for. It would be unable, for instance, to identify the root cause for a latency spike due to LLC evictions caused by a noisy neighboring process, since PIX does not account for contention.

This example illustrates how PIX can help focus the operators' attention on likely explanations for the performance they observe, thereby reducing the amount of work needed to find the root cause.

In conclusion, our evaluation shows that PIX is practical: the complexity of extracted interfaces is significantly lower than the NF implementation, their accuracy is high, and the time taken to extract them is reasonable. Further, NF developers and operators can use these interfaces to identify performance regressions, diagnose and fix performance bugs, and pick the NFs that are best suited to their hardware.

5   Does PIX Generalize?

In this section, we explore how PIX can generalize in two directions: (1) programs other than NFs, that are nevertheless still amenable to ESE; and (2) NFs that are not amenable to ESE. Overall, we find that the design of PIX—split into a modular back-end and front-end that produce general-case and deployment-specific interfaces, respectively—enables generalization by adapting just the necessary modules in the PIX pipeline.

Beyond NFs: We have successfully applied PIX to the OpenSSL library, to uncover digital side-channels, and to eBPF extensions for user-space file systems.

Extracting interfaces for finding digital side-channels required modifying only PIX's hardware model (i.e., step 1 in the back-end). Implementing a new model focused on sources of constant-time violations (using the exhaustive list in [3]) took us 2 person months. We ran PIX on 12 cryptographic primitives from OpenSSL 3.0 [61] and found a constant-time violation in the AES cipher unpadding function. This violation was acknowledged by the OpenSSL maintainers [62]. We have submitted a pull request [63] that has undergone multiple rounds of review and is in the final stages of getting merged.

Our experience with OpenSSL reinforced our belief (from §4.2.1) that a tool that automatically extracts performance interfaces would be of great use to developers. For example, we learned that the violation we uncovered had been latent since OpenSSL 1.1.1 because the developer "just reused the code" and had somehow been missed despite the extremely thorough code reviews that OpenSSL goes through. If performance interfaces of the OpenSSL code were extracted regularly, e.g., as part of continuous integration, it is unlikely that this violation would have persisted for this long.

Extracting interfaces for eBPF file system extensions was more straightforward since the code is similar to that of eBPF NFs. Here, we only had to add translation rules (step 2 in the PIX back-end) corresponding to the supported system calls. This took 4 person-days, after which PIX was able to automatically extract interfaces for the extFUSE extensions [7].

Code not amenable to ESE: To evaluate the limits of PIX's ESE-based approach, we used PIX on Snort [73],

a popular IDS that independent prior work has shown to not be amenable to ESE [53, 81]. Our results corroborated those from prior work; while PIX did extract performance interfaces for the networking stack and all detection rules that look only at packet headers, attempting to extract a complete interface caused PIX to time out. Extracting an interface from Snort with PIX requires either that we modify its code to cleanly separate the stateful components, or that we replace Bolt in the PIX back-end with a manual theorem prover.

6   Related Work

We compared PIX to Bolt [41] w.r.t the design (in §2) and results (in §4.1). We do not do so again here.

Here we provide a qualitative comparison of PIX against Freud, Appendix A provides a detailed quantitative one. Freud treats code almost as a black box and relies on developers to provide comprehensive performance test suites in order to guide the exploration of performance behaviors and ensure prediction accuracy. PIX is white-box because it analyzes source code. Analyzing the source ensures that PIX can analyze the system once, and instantiate the interface for different deployments, while Freud users must re-run the tool for each new <workload, hardware> pair. Lastly, Freud's performance formulae are limited to being expressed in terms of program variables, but the performance of stateful code typically depends on (implicit) PCVs instead [37, 38].

Performance upper bounds and adversarial workloads: Worst-Case Execution Time (WCET) Analysis derives formal upper bounds on performance; [79] provides an overview of the state of the art. These bounds are particularly popular in the domain of real-time and safety-critical systems where performance guarantees are a part of functional correctness. While WCET only looks at one aspect of the performance profile—the absolute worst-case—performance interfaces characterize performance in the face of any arbitrary input, whether typical, ideal, or adversarial. Further, to enable stringent upper bounds, real-time systems tend to avoid dynamic data structures and input-dependent memory accesses—aspects that are commonplace in NFs.

Considerable prior work focuses on generating and analyzing adversarial workloads that attack software performance [2, 18, 49, 60, 64, 65, 67, 72, 76]. As with WCET, all of this work focuses only on worst-case inputs, while interfaces reflect the entire performance profile.

Performance profilers: Traditional profilers [51] measure the execution cost (e.g., running time, executed instructions, cache misses) of a piece of code. Trend Profiling [34], Algorithmic Profiling [85] and Input-Sensitive Profiling [16, 17] take this one step further: by extracting a cost function defining the relationship between input

size and execution cost. However, like Freud, these tools treat the code as a black-box and require developers to provide comprehensive performance test suites to guide the exploration of performance behavior.

Performance analysis for SmartNIC-based NFs: Krude et al. [47] use SMT solvers to analyze NF code written for processor-based SmartNICs and provide lower bounds on throughput. Focussing solely on throughput lower bounds results in their approach being limited to analyzing worst-case latency, much like WCET. Clara [68] uses machine learning to analyze NF code written in C to identify "effective porting strategies" that result in low latency when the NF is ported to a SmartNIC. Unlike PIX that focusses on accurately predicting the NF latency, Clara focusses on identifying how the NF implementation can make best use of the SmartNIC hardware (e.g., accelerator usage, NF state placement strategies, etc).

Program analysis for NF code running on commodity hardware: Several instances of prior work have proposed using program analysis to help understand, debug, and verify the semantic behavior of software NFs [10, 11, 19, 44, 66, 74, 84, 86]. PIX builds upon the experience of all of this prior work, but analyzes NF performance.

NF performance monitoring and diagnosis: Several instances of prior work [28, 35, 56, 80] diagnose performance issues such as packet drops or low throughput in NF deployments. Such work is complementary to PIX since it helps diagnose performance issues once they occur in production, while PIX provides a summary of NF performance before the NF is deployed.

7 Conclusion

We proposed the notion of a *performance interface*—a program that accepts the same inputs as the system and outputs the latency incurred by the given input. For the interface to be simultaneously simple, accurate and human-readable we proposed (a) the notion of a *performance resolution* to eliminating unnecessary details, and (b) separate *deployment-specific interfaces* to tailor the interface to particular <workload, environment> pairs.

We described a tool (PIX) that automatically extracts performance interfaces from NF implementations. and evaluated it on 12 NFs, including several used in production. Our results show that PIX is practical—the complexity of extracted interfaces is significantly lower than the NF implementation, their accuracy is high, and the time to extract them is reasonable. Finally, we show how NF developers and operators can use these interfaces today, to identify performance regressions, diagnose and fix performance bugs, and pick the NFs that are best suited to their hardware.

Appendix A   Using Freud on NFs

In this section, we describe our experience experimenting with Freud. We used the publicly available Freud code [30] at commit ID e6e7a91006.

Freud takes as input a binary and a test suite, and outputs an expression of performance (runtime) as a function of input and global variables. So, by design, it strikes a different generality/accuracy balance than PIX: It is more general, in the sense that it can run on any program—not just NFs that are amenable to ESE—and requires no source code and no data-structure pre-analysis. It is less accurate, in two ways: (a) It cannot reason about the performance of execution paths that are not triggered by the test suite (since it does not symbex the program, and it does not analyze the source code). (b) It cannot reason about how past inputs affect performance in stateful code (since it does not know anything about the data structures where the state is stored).

To assess Freud's generality/accuracy balance, especially in the context of NFs, we used it on three classes of programs: (a) A stateless program that spins for a period of time proportional to the input length. (b) Data structures commonly used by NFs: a longest prefix match (LPM) trie and a hash map. (c) NFs: VigNAT (academic prototype), Natasha (production NAT used at ScaleWay), and Maglev (DPDK implementation of Google's load balancer). Natasha comes with an open-source performance test suite [57], making it an ideal fit for Freud. For the remaining programs, we used as test suites the packet traces on which we evaluated PIX.

Table 10 summarizes our results, discussed below.

Freud mode	Program	Accurate annotation?
Freud-vanilla	Synthetic stateless NF	Yes
	LPM trie	No
	Hashmap	No
	Real NFs	No
Freud-nf	Synthetic stateless NF	Yes
	LPM trie	Yes
	Hashmap	No
	Real NFs	No

Table 10. Summary of our experiments with Freud.

Freud-vanilla: First, we ran Freud on unmodified programs, and it behaved as expected: It successfully characterized the spinning program's runtime as a function of the input length, but it could not produce meaningful performance annotations for the data structures or NFs. This is normal, since, in the latter programs, runtime is a function of implicit variables that capture the interaction between current and past inputs (e.g., number of iterations of `while(bucket[i].is_full ==1)`).

Freud-nf: Next, to compare with PIX more fairly, we explicitly modified our programs to work with Freud: we identified conditions that we knew impacted performance (essentially PCVs) and manually added them as global variables (which Freud tracks). For instance, in the hashmap, we added a global variable to explicitly track the number of collisions; in the LPM trie, we added a global variable to explicitly track the depth traversed.

The results for the data structures were mixed: For the LPM trie, Freud produced an accurate performance annotation. For the hashmap, Freud mistook a correlation for a causation: when a test caused every packet to experience a collision, Freud concluded that runtime was determined by occupancy, as opposed to the number of collisions. We expect that this issue can be resolved at the cost of extra developer effort (to produce a smarter test suite).

For the real NFs, Freud could not produce meaningful performance annotations (despite our modifications to the NF source code). This is not surprising, given that Freud does not analyze the source code, hence is unable to track how a sequence of state-accessing calls affects runtime. For instance, in Maglev, known client packets that are destined to a now-stale backend-server undergo consistent hashing once again, to pick a new backend. Since Freud does not analyze the source code, it cannot track how this call sequence affects runtime, looking instead to express runtime as a function of individual variables—which does not work. We observed similar scenarios in the other NFs.

Conclusion: In its current form, Freud cannot produce accurate performance annotations for stateful NFs. To do so, it would need to track how a sequence of state-accessing calls affects performance. We think that that would necessarily require (a) some assumption about the

structure of the code (akin to our clean state assumption), (b) a nuanced test suite for the NF's data structures to reveal which aspects of state affect performance (which is done, in our approach, with the manual extraction of PCVs during pre-analysis), and (c) leveraging call context. We think that adding these elements to Freud would bring it very close to PIX; we expect it would achieve similar accuracy, but at the cost of its current generality.

Appendix B   Accuracy of performance interfaces

This section provides more detailed answers to the following questions: (1) What is the prediction error for both PIX and Bolt for each individual NF? (2) What is the prediction error for both PIX and Bolt as a function of the percentile latency?

Prediction error for individual NFs: Table 11 provides detailed per-NF results for PIX's prediction accuracy for hardware-independent metrics, i.e., x86 instruction count and x86 memory accesses. We see that the results are similar across all the NFs, with PIX consistently outperforming Bolt.

NF	Spade Prediction Error		Bolt Prediction Error	
	x86 instructions	x86 mem-ops	x86 instructions	x86 mem-ops
VigNAT	1.2%	1.3%	3.1%	4.0%
Bridge	0.8%	1.1%	3.6%	3.6%
Maglev	1.1%	1.1%	5.1%	4.2%
Router	1.7%	3.9%	6.8%	6.1%
Policer	1.4%	1.7%	4.2%	5.1%
Natasha	2.6%	3.2%	5.1%	5.6%
DPDK NAT	0.9%	1.1%	2.3%	2.9%
DPDK FW	1.1%	1.4%	2.7%	3.7%

Table 11. Prediction error for median latency for x86 instruction count and memory accesses for all 8 DPDK NFs in the deployment characterized by the typical traffic. The numbers for adversarial traffic are similar.

Figure 10. PIX's average prediction error for CPU cycles across two deployments as a function of the percentile latency
Figure 11. Bolt's average prediction error for CPU cycles across two deployments as a function of the percentile latency

Prediction error as a function of the percentile latency: Fig. 10 illustrates PIX's average prediction error across all 8 NFs for each deployment. First, we see that the average error shows similar trends across deployments, proving that PIX characterises the deployment-specific workload correctly. Second, we see that for both deployments the average error is more or less stable at around 8% up to the 95th percentile showing that for these percentiles, PIX characterises the interaction of the NF with the hardware correctly. Lastly, we see that at the tail, the prediction errors become negative. This is due to the fact that the simple HW model that PIX employs (*instructions * CPI + LLC_misses * miss_latency*) is invalid at the tail, where other hardware aspects kick in.

Fig. 11 illustrates Bolt's average prediction error across all 8 NFs for each deployment. Bolt estimates only worst-case latency and this is evident in the results—note the change in scale on the y-axis from Fig. 10. For all percentiles except the tail, Bolt is widly inaccurate with errors up to 900%. On the other hand, Bolt does not underestimate latency at the tail since it accounts for myriad worst-case scenarios in the underlying hardware worst-cases that PIX ignores to ensure accuracy across the remainder of the spectrum.

Automated Verification of Network Function Binaries

[+]EPFL   [°]Citrix Systems

Abstract

Formally verifying the correctness of software network functions (NFs) is necessary for network reliability, yet existing techniques require full source code and mandate the use of specific data structures.

We describe an automated technique to verify NF binaries, making verification usable by network operators even on proprietary code. To solve the key challenge of bridging the abstraction levels of NF implementations and specifications without special-casing a set of data structures, we observe that data structures used by NFs can be modeled as maps, and introduce a universal type to specify both NFs and their data structures, the "ghost map". In addition, we observe that the interactions between an NF and its environment are sufficient to infer control flow and types, removing the requirement for source code.

We implement our technique in KLINT, a tool with which we verify, in minutes, that 7 NF binaries satisfy their specifications, without limiting developers' choices of data structures. The specifications are written in Python and use maps to model state. KLINT can also verify an entire NF binary stack, all the way down to the NIC driver, using a minimal operating system. Operators can thus verify NF binaries, without source code or debug symbols, without requiring developers to use specific programming languages or data structures, and without trusting any software except KLINT.

1 Introduction

Network operators are moving from hardware *network functions* to software ones for flexibility, but still deploying them as black boxes. Historically, network functions such as firewalls, NATs, and load balancers used special-purpose hardware for performance at the cost of flexibility, but this trade-off does not always make sense any more thanks to the performance of modern general-purpose hardware. Developers write software network functions using programming languages such as C or Rust and frameworks such as DPDK [15] or BPF [11, 33]. Marketplaces for distribution of software network functions are emerging [18], and most network functions on these marketplaces are proprietary and distributed in binary form.

Developers and operators currently test network functions hoping to catch bugs, but this is not enough especially in light of frequent software updates. For instance, network address translators from Microsoft [36], Linux [37], and Cisco [38] have had headline-causing bugs and vulnerabilities.

```
function Firewall_Check(packet, flow_table)
    if packet.device.is_internal then
        assert packet.is_forwarded
        if packet.flow not in flow_table then
            assert flow_table.was_full
    else
        if packet.is_forwarded then
            assert packet.flow in flow_table
```

Algorithm 1: Specification for a firewall. The firewall must remember flows exiting the network and must only allow packets in an existing flow to enter the network.

Operators need guarantees that the software network functions they deploy conform to specifications, instead of relying on tests. Consider the specification for a firewall in Algorithm 1, which will be our running example. This specification restricts what a firewall can do but does not state exactly how a firewall should be implemented. It also hides details irrelevant to operators such as packet parsers and policies to expire old flows. If an implementation could be *verified* to conform to this specification no matter what, an operator could deploy that implementation with confidence.

Developers need to provide proofs of functional correctness but do not always want to disclose their source code, meaning verification must be done on binaries. This requirement is driven by the way software is distributed to operators, but it also means developers do not need to restrict which programming languages they use nor worry about latent bugs in the tools they use such as compilers. A tool that can verify binaries can be used by operators regardless of whether they have access to source code and regardless of which language and toolchain developers used. Thus, even for open-source code, verifying binaries helps developers by enabling them to use any language and toolchain, even those considered experimental, since they can provide guarantees about the compiled binary to operators.

Developers currently cannot provide proofs (1) of functional correctness, (2) without source code, and (3) without verification expertise. They can use the Linux kernel's automated BPF verifier, but only for low-level properties such as memory safety. They can use Vigor [53] or Gravel [55] to automatically prove functional specifications, but both rely on typing information and thus require source code or an intermediate representation that can be reverse-engineered. Vigor and Gravel also limit developers to specific data structures; while developers could add new ones to the tools, they generally lack the verification expertise to do so. What remains is conventional testing, which can only show that a binary works in specific cases, not provide guarantees.

Verification of data structures is out of scope for this paper. We assume that data structure code in binaries is clearly delineated and that it correctly implements its API and specification. Developers should then be able to write code using any data structure they want. A verification tool for network functions must understand the semantics of data structures through some form of contract, and automatically reason about their contents without requiring proof annotations. Developers who wish to provide maximal guarantees can manually verify their data structures, or use existing verified ones, but this should not be required for network function code to be automatically verifiable.

Our goal is to design a tool to automatically prove that a network function binary conforms to a specification, given data structures assumed to be correct. The inputs to this tool are a binary with explicit calls to data structure operations, contracts for these operations, and a specification such as a formalization of an RFC or IEEE standard. The output is a proof that the binary refines the specification or a counter-example that demonstrates otherwise.

Verifying arbitrary binaries is hard since type and control flow information are critical to verification but hard to obtain without debug symbols. However, network functions are not arbitrary. They commonly confine complex code to well-defined data structures, such as BPF maps [2], and only have a handful of well-defined interactions with their environment, such as transmitting packets and reading system time. These two observations lead to two ideas enabling us to verify network function binaries.

First, we use maps as a "universal" data structure to specify network functions and data structures. We define the abstract state of both network function specifications and data structure contracts in terms of maps from keys to values using a programming language such as Python. We call these maps *ghost maps* by analogy to "ghost variables" that exist only in proofs, not in implementations. Contracts can be written even for data structures that cannot be implemented in terms of maps, by using "for all" quantifiers to describe an operation's effects on the data structure in a declarative manner without describing its implementation. Verification is thus proving that the binary manipulates concrete data structures in a way that conforms to the manipulation of abstract maps in the specification, using contracts to match concrete operations with abstract ones.

Ghost maps enable efficient and automated invariant inference. Inferring invariants ensures automated analysis does not explore impossible program states, which would cause spurious verification failures. The sweeping simplification of maps enables our tool to reason about invariants across any data structures instead of limiting itself to specific ones. It also leads to the tool being simpler, as there is only one kind of data structure to reason about, the map. The tool translates data structure operations into map operations and infers invariants on the resulting maps.

Second, we infer typing and control flow information from environment interactions. Modeling network functions' environment precisely is feasible since it is small and well-defined. Typing information at the boundaries between a binary and its environment is enough, since specifications are defined in terms of environment interactions: maps and fundamental operations such as packet transmission.

We have built KLINT, a prototype of our technique. It takes in a binary without debug symbols, a Python specification of its semantics, and Python contracts for its data structures. The contracts only need to be written once per data structure implementation, as a more precise form of the documentation developers currently write. KLINT always terminates with either a proof or a counter-example, unless the processing of a single packet does not terminate, in which case KLINT fails after a user-defined limit. KLINT can verify an entire software stack using a minimal operating system if needed. KLINT can verify code written in different languages, such as C or Rust, on different frameworks, such as DPDK or BPF, and deployed in different contexts, such as virtual machines, containers, or raw hardware. Developers can use any data structure as long as it has Python contracts, even if the data structure implementation is not verified. The code of the verified network functions is *verification-agnostic*: only the standard programming practice of separating data structures from other code and documenting their specifications is necessary.

We use KLINT to verify network functions we write based on those from Vigor [53] and to verify existing BPF network functions such as Facebook's Katran [47]. KLINT can prove a range of properties, from full functional correctness according to a specification, to memory safety and crash freedom for functions without a high-level specification such as Katran. For instance, we extract a specification from IEEE 802.1D [30] for a bridge we write. We provide a detailed list of properties we verify using KLINT in Appendix A. Using KLINT gives operators guarantees about the correctness of any binary they deploy: either KLINT finds bugs, which can be reported to developers, or it finds no bugs, providing a guarantee the binary conforms to its specification.

In summary, our contributions are (1) a technique to reason about data structures and infer invariants based on the idea of "ghost maps" and (2) KLINT, a prototype that uses map-based reasoning to automatically and efficiently verify network function binaries that use trusted data structures with map-based contracts. We use KLINT to verify the functional correctness of 7 binaries, 6 written in C and 1 in Rust, in minutes. These verified binaries run faster than previous verified ones thanks to relaxing restrictions imposed by previous work. We also verify the memory safety and crash freedom of 5 existing BPF network functions using KLINT, though we have no specifications for them.

The code for KLINT and our network functions is publicly available at https://github.com/dslab-epfl/klint.

2 Design Insights

We formalize what we mean by a "network function" in §2.1, explain how environment interactions are enough to infer typing and control flow information of binaries in §2.2, and describe how we bridge the gap between implementations and specifications through the indirection of maps in §2.3.

2.1 Network functions we target

We restrict ourselves to network functions that use mutable state to process packets and contain two phases: initialization and packet processing. When processing a packet, network functions decide whether to transmit packets in response and what data to transmit based on state and on the packet's contents and metadata, such as its length. We assume that network functions are single-threaded, and that they only execute code when initializing and receiving packets. We do not support timers as triggers to run code; they must instead be checked during packet processing.

To create, read, and update state, network functions acquire and use data structure *capabilities* through an environment, such as the DPDK [15] framework. These capabilities correspond to opaque pointers in C, preventing network functions from directly accessing data structure internals.

Acquiring capabilities is only allowed during initialization, and may fail due to external factors, for instance running out of memory. Using capabilities is allowed at any time, and may only fail through incorrect use, for instance indexing arrays out of bounds. Packet processing may also use other environment calls that cannot fail from external factors, such as obtaining the current time.

Our assumptions about data structures correspond to good programming practices: developers should use data structures in a modular fashion for maintainability, and network functions should not allocate memory while processing packets, to avoid performance issues and out-of-memory errors that could allow for denial-of-service attacks.

We represent our model of a network function in Figure 1. This is only a formalization of what developers already do, not a proposal of a new model.

Figure 1. Network function components: initialization allocates state, packet processing reads and writes state and may also use other utilities. Arrows represent control flow.

2.2 Information from environment interactions

The first limitation of previous work that we overcome is the need for source code, thanks to the insight that environment interactions are sufficient to infer all necessary information about network function code, i.e., types and control flow.

As we described in §2.1, the only way for a program to hold state and interact with the external world is through its environment, such as displaying information or receiving a packet from the network. That is, we define the environment to be low-level enough that programs can be modeled as pure functions that compose environment interactions.

A tool can precisely infer all possible behaviors of a program by replacing the program's environment with one that can exhibit any allowed environment behavior, not a specific one. This verification-only environment can be written by hand or inferred from machine-readable documentation.

Writing an exhaustive model of the environment is not feasible for general-purpose software because its environment is large and ill-defined. There is no formal definition of large environments such as operating systems, and documentation often omits implementation details of high-level operations that programs may rely on in practice.

However, a complete environment description is feasible for network functions, because their environments are small and well-defined. Formally defining all environment interactions is manual work but must only be done once by an environment's developers, and the operations are low-level enough that emulating all possible implementation-specific behaviors is feasible. Having a small and well-defined environment also means that its modules can be formally verified manually if its developers choose to do so, enabling verification of the entire software stack.

For instance, our example firewall calls a data structure library to perform a lookup in its flow table and calls a networking framework such as DPDK to forward or drop the packet based on the lookup result. Both the data structures and the networking framework are part of the environment, and both can be precisely replaced by a tool as long as the network function uses dynamic linking.

Environment interactions can be observed on binaries without loss of information, since the tool knows the number of parameters and their types. For instance, when a binary calls DPDK's packet transmission function, the tool uses the current architecture's calling convention, which is known, and the data types in DPDK's headers, which are publicly available, to extract the arguments to the transmission function from the current machine state, such as the packet buffer and metadata. Thus, source code is not necessary for automated software network function verification.

The control flow information necessary for verification can be similarly extracted by observing which branches are taken or not between environment interactions, which produces an "unrolled" version of the true control flow graph.

2.3 Using maps to bridge the gap

Verifying the correctness of a network function that satisfies the definition in §2.1 consists of showing that the semantics of the code, obtained from environment interactions as described in §2.2, match the semantics of the specification. However, there is a gap between the variety of data structures that exist in the code and the restricted set of abstractions that any given tool can reason about, as we illustrate in Figure 2.

For instance, our firewall may use a "least recently used" data structure to keep track of which packet flows should be expired due to a lack of activity, with operations such as "add a new item" and "remove and return the oldest item". The firewall may also combine the use of this data structure with other structures, such as a map tracking per-flow statistics or a configurable set of ports that are open to the external world at all times.

Previous work proposed two ways to bridge the gap between implementation and specification: Vigor [53] requires the use of specific data structures in both implementation and specification, while Gravel [55] requires the use of specific data structures that it knows how to model in terms of high-level operations that can be used in specifications.

Vigor imposes two constraints to verify our firewall. First, the firewall must be written using data structures that Vigor knows about, either by modifying the firewall's code to only use Vigor data structures or by modifying Vigor itself to handle new data structures, including proof annotations for invariants that can hold across these data structures such as "all flows in the LRU are also in the map". Second, the firewall specification must be written in terms of the same data structures used in the implementation. These two constraints limit both developers and operators. Developers must restrict themselves to specific data structures or learn verification techniques to add new ones, and operators must learn the semantics of the data structures used in an implementation to understand its specification.

Gravel removes the second limitation: it translates data structure operations to a small set of high-level operations for use in specifications, thus operators do not need to learn all data structure semantics.

Implementation   *Specification*

```
map->get(pkt->flow, &v)
        ↓
lru->update(v, time())    ↕?    if packet.flow in table:
        ↓                            assert sent == [packet]
    transmit(pkt)
```

Figure 2. There is a gap between the abstractions used in the implementation and the specification.

However, the restriction on developers remains. Developers must either modify the firewall's code to only use existing Gravel data structures or modify Gravel itself to handle new data structures.

Fundamentally, tools that handle a specific set of data structures do not scale. Adding support for a new data structure requires not only encoding the data structure's operations, but also its interactions with other data structures, such as invariants that can exist across structures. Even if a tool is limited to invariants across two data structures, adding the Nth structure requires adding N kinds of invariants, one for each data structure including the new one.

We introduce a level of conceptual indirection: we express the semantics of both data structures and specifications in terms of one data structure, the *map*. Operations on data structures such as arrays, hash tables, longest-prefix-match tables, and port allocators can be defined in terms of map operations, regardless of how they are implemented. Verification tools can use contracts to translate any data structure operation into map operations, which become the only kind of operation the tool needs to reason about for invariant inference and verification.

We refer to such maps as *ghost maps*, by analogy to "ghost variables" which are variables only used in proofs. We present an example of contracts for a "least recently used" data structure in Listing 1. Using this contract, a verification tool can translate the LRU semantics into maps, and thus does not need special knowledge of what an LRU data structure is, only knowledge of maps. Importantly, contracts can be declarative, not just imperative. Ghost maps can define even data structures that cannot be implemented using maps thanks to the "for all" quantifier. LRU_expire's contract only describes *what* it does, not *how*: the returned value is the oldest, but the contract does not need to explain how this value is found. We explain how a verification tool can efficiently reason with maps in §3.

This sweeping simplification also makes invariant inference easier since there is only one kind of data structure, as we show in §4.

```
1  # struct LRU;
2    LRU = namedtuple('LRU', ['items'])
3  # void LRU_add(struct LRU* lru,
4  #              void* item, int age);
5    assert item not in lru.items
6    lru.items[item] = age
7  # void* LRU_expire(struct LRU* lru);
8    age = lru.items[result]
9    assume(lru.items.forall(lambda k, v: v <= age))
10   lru.items.remove(result)
```

Listing 1. Contracts defined using maps, in Python, for a "least recently used" data structure, in C. result is the return value from LRU_expire.

3 Ghost Maps

To verify network functions automatically, we use *symbolic execution* to analyze all their paths, which we summarize in §3.1. Since data structure implementations have too many paths to enumerate, we abstract them using *contracts* instead, to obtain paths such as "key found" and "key not found" instead of one path per cell in which a key might be.

We introduce ghost maps as a "vocabulary" in contracts to describe the semantics of data structures and network functions to both verification tools and human readers. Ghost maps only exist within contracts, not implementations.

We describe our goals for ghost maps in §3.2, our proposed representation of ghost maps in §3.3, and our proposed translation of their operations into logical formulas in §3.4.

3.1 Symbolic execution background

A *symbolic execution engine* executes code with *symbols* as inputs instead of concrete values. Whenever it encounters a branch on a symbolic condition, it explores both alternatives, remembering the choices it made in a *path constraint*. This leads to a set of *paths*, which are sequences of choices that each represent one possible program execution. For instance, instead of executing an "absolute value" operation on -5 and obtaining 5, a symbolic execution engine will execute it on α and obtain two paths: one with path constraint $\alpha \geq 0$ and result α, and one with path constraint $\alpha < 0$ and result $-\alpha$.

Some code has too many paths to explore in reasonable time. For instance, consider looking for a value in an array. The value could be in the first position, or the second, or the third, and so on, until the array length. The number of paths is limited by the array length, which could be, e.g., 2^{32}. If the code which looked up the value then looks up another value, each path resulting from the first lookup will lead to new paths for the second lookup, squaring the total number of paths. This problem is known as *path explosion*. While the number of paths can sometimes be reduced by merging related paths at the expense of producing more complex constraints [29], the paths to be merged must still be partially explored, which does not solve path explosion.

If the number of paths in a program is "reasonably" small, a symbolic execution engine can exhaustively enumerate them and verify the program by verifying that each path satisfies the program's specification.

Figure 3. Ghost maps are more expressive than bitvectors while remaining decidable, unlike more powerful theories such as arrays with universal quantifiers.

$$length(M) \rightarrow Int$$
$$get(M, K) \rightarrow V \mid None$$
$$set(M, K, V) \rightarrow M'$$
$$remove(M, K) \rightarrow M'$$
$$forall\big(M, \lambda(k, v) \rightarrow Bool\big) \rightarrow Bool$$

Listing 1. Ghost map operations. M and M' are maps; K, V are keys and values. *Int* denotes bitvector-based integers, and *Bool* Booleans. *None* is the lack of value.

3.2 Expressivity, decidability, and completeness

We propose the ghost map abstraction in Listing 1 which is expressive enough to define data structures and network functions, while still enabling a tool to reason in a decidable, sound, and "complete enough" manner. We describe each of these properties next.

Ghost maps are *expressive* enough to abstract the data structures we care about. Simpler abstractions require too much detail in contracts to be practical for either humans or tools. For instance, representing a hash table as a sequence of 0s and 1s is possible but impractical. We are concerned with data structures used in network functions, such as hash tables and port allocators, thus we limit our vocabulary to what they need, not to all possible code.

However, expressiveness is at odds with *decidability*. Symbolic execution engines use a solver to tell whether a logical formula is *satisfiable*, i.e., whether there exists an assignment of variables such that the formula holds. For instance, if "the firewall's variables, given the firewall's constraints, violate its specification" is satisfiable, then the assignment of variables is a counter-example to the firewall's correctness. Logical formulas are written using *theories*, which are the "vocabulary" of solvers. Some theories are *decidable*, meaning that a correct solver will always return a correct answer. Some are not, meaning that the answer may be "unknown" instead of yes or no. Even with decidable theories, "unknown" may be returned if the solver is given a timeout and cannot find an answer in time.

Verification tools must be *sound* and as *complete* as possible. A tool is sound if it verifies *only* correct programs. A tool is complete if it verifies *all* correct programs. Due to the Halting Problem [49], verification of general-purpose programming languages must be incomplete, thus the goal is to verify "interesting" correct programs, i.e., those that humans actually write, even if some contrived theoretical examples cannot be verified.

Ghost maps are an intermediate step between quantifier-free bit vectors, which are decidable due to their finite size but not expressive enough, and arrays with universal quantifiers, which are more than expressive enough but undecidable, as we illustrate in Figure 3.

3.3 Representing ghost maps

To remain as decidable as the theory of bit vectors while offering more expressivity, we present a translation of ghost maps to bit vectors in the context of symbolic execution. Notably, ghost maps' "for all" quantifier, which enables non-imperative contracts for data structures that cannot be implemented with maps, can be translated *without* using universal quantifiers. Ghost maps can be more expressive despite being translated to bit vectors because the symbolic execution engine internally uses data structures, such as lists, to build the logical formulas it sends to the solver.

We expect the code to manipulate maps of large size, but to only interact with a small number of items in any given map. This is true of network functions, which by nature only perform a small number of operations for each packet to remain within their performance budget.

Tracking *known* and *unknown* items separately is our key insight to handle maps of arbitrary size. That is, none of the map operations require "forking" the current path, and the engine handles map operations in a time linear in the number of known items, not total items.

Thus, instead of keeping track of every item in every map, the engine only needs to track the specific items that are explicitly used in one iteration of the network function's packet-processing loop. Other items are "summarized" into a single pseudo-item that tracks their constraints, such as "all unknown values are non-zero".

This scheme naturally enables ghost map lengths to be symbolic, since their actual size does not matter as much as the number of known items. A verification tool can thus represent maps whose length is determined by configuration parameters using a symbolic configuration, instead of verifying only one specific configuration as is for instance done in Vigor [53]. The tool can thus catch all bugs that only occur in specific configurations, such as the maximum capacity of the firewall's flow table being zero, without requiring developers to think of which configurations to try.

Counter-intuitively, the engine must mutate its internal representation of maps during read-only operations on maps. Known items must include those that have been retrieved from the map, even if they have not explicitly been set before. For instance, consider the following:

$$get(M, K_1) \rightarrow V_1$$
$$get(M, K_2) \rightarrow V_2$$

If $K_1 = K_2$, then $V_1 = V_2$ by definition. But the engine must remember the first *get* in some way in order to guarantee the implication, and it cannot store high-level map operations in the path constraint, thus it must modify its internal representation of M. From an outside perspective, M has not changed, but internally the engine must remember this *get*.

We informally describe each operation first, then add additional details to handle subtleties, then provide a formal algorithm for the core *get* operation.

The engine tracks each map's length explicitly.

Known items are triples: (key, value, presence bit). If the presence bit is *false*, the value is ignored and the key is considered absent from the map. *None* only exists conceptually; the theory of bit vectors cannot represent it.

Known items may be redundant, but their values and presence bits must match if their keys match. This is because their keys may be symbolic, thus the engine cannot know for sure whether two items have equal keys.

Unknown items are represented by an *invariant* that they all satisfy. The unknown items invariant only concerns unknown items. Known items need not satisfy it. For instance, a map may have as invariant "all unknown values are non-zero" and two known items, $(K_1, 0, true)$, $(K_2, 1, \alpha)$. The first known item is definitely present, whereas the second may or may not be present depending on the value of α.

The unknown items invariant is represented as a formula on a special *unknown item*, unique to each map. For instance, the non-zero invariant example is represented as $UP_M \Rightarrow UV_M \neq 0$, where UP_M and UV_M are the presence bit and value of M's unknown item. Including the presence bit in the invariant allows it to be constrained for cases such as arrays. For instance, a zero-based array of length L described using a ghost map A would have $UP_A = (0 \leq UK_A < L)$ as part of its unknown items invariant, indicating that keys are in A if and only if they are between 0 and L, matching the semantics of array indexing in languages such as C.

3.4 Translating ghost map operations

We use $ITE(c, t, f)$ to denote "if c then t else f", and *fresh* to mean a symbol that was not used before, i.e., that is not constrained in any way. "Applying" the unknown invariant of a map to an item means substituting the map's unknown item for the item.

$length(M)$: Return the map's length, which the engine tracks explicitly.

$get(M, K)$: Create a fresh tuple (V, P). Add (K, V, P) to the map's known items. Add constraints to the current path to encode that, within the map, (1) if K matches a known item then so do V and P, (2) if K does not match any known item then the unknown items invariant applies on (K, V, P), and (3) the number of unique known items cannot exceed its length. Return (V, P), which encodes "if P then V else *None*".

$set(M, K, V)$: Let $(\_, P) = get(M, K)$. Return a new map whose length is $length(M) + ITE(P, 0, 1)$, whose known items are $(K', ITE(K = K', V, V'), P' \vee (K = K'))$ for each known item (K', V', P') in M, plus $(K, V, true)$, and whose unknown items invariant is the same. That is, (1) the length only grows if K was not in M, and (2) known items must match if they are redundant.

$remove(M, K)$: The opposite of *set*, i.e., the length change is $ITE(P, -1, 0)$, the new known item is $(K, V, false)$, where V is any arbitrary value, and the known items are changed to $(K', ITE(K = K', V, V'), P' \wedge (K \neq K'))$.

$forall(M, F)$: The result is *true* iff $P \Rightarrow F(K, V)$ for each known item (K, V, P) in the map and $UP_M \Rightarrow F(UK_M, UV_M)$ for the unknown item of the map. That is, the result indicates whether the predicate holds on known items and on unknown items. Add to the map's invariant that if the result of this operation is *true*, then the predicate holds on unknown items if their presence bit is *true*, ensuring that even if the result is not yet known, it will be consistently applied in the future. If the result is false, future items are not constrained, which is sound but not complete.

***Layers* are necessary to handle dependencies** that arise when code uses multiple versions of a map at once. Consider:

$$set(M, K, V) \rightarrow M' \quad \begin{array}{l} get(M, K') \rightarrow V' \\ get(M', K') \rightarrow V'' \end{array}$$

If $K \neq K'$, then V' and V'' must be the same, since only the value associated with K is affected by the *set*. However, the representation described earlier cannot guarantee this, because the known items of M and M' are independent.

To handle this issue, *set* and *remove* return layers instead of entirely new maps, as the example in Figure 4 illustrates. That is, they return a map which includes the newly added or removed item among its known items, but which links to the previous map for the other known items, transforming them when necessary, instead of evaluating the new known items at creation time. Items and invariants created by *get* and *forall* are always added to the bottom-most layer. Map layers also share the unknown items invariant, and the associated "unknown item", of their base map.

Thus, in our example above, the known items "seen" by the second *get* operation include the result of the first one, and thus the second *get* will return a result that lets a tool prove $K \neq K' \Rightarrow V' = V''$.

Invariant recursion must be explicitly handled to avoid infinite recursion when two maps' invariants refer to each other. For instance, a bi-directional map may be represented as two maps whose contents are inverses: for each key-value pair (K, V) in map M_1, there is a pair (V, K) in map M_2, and vice versa. The invariants are:

$$forall(M_1, \lambda(k, v). \; get(M_2, v) = k)$$
$$forall(M_2, \lambda(k, v). \; get(M_1, v) = k)$$

Consider what would happen using the representation described earlier when the engine handles $get(M_1, K)$ for some K. As part of adding the invariant on the newly-known item of M_1 to the path constraint, the engine will call $get(M_2, V)$ with the fresh V from the original *get*. As part of adding the invariant on the newly-known item of M_2 to the path constraint, the engine will call $get(M_1, V')$ with the fresh V' from the second *get*. The engine then calls *get* on M_2, and so on, leading to infinite recursion.

Solving this issue requires the engine to recognize that in the third *get* call, the V' argument is equal to K, which it knows from the first *get* call. The result should thus be the existing V, not some fresh V''.

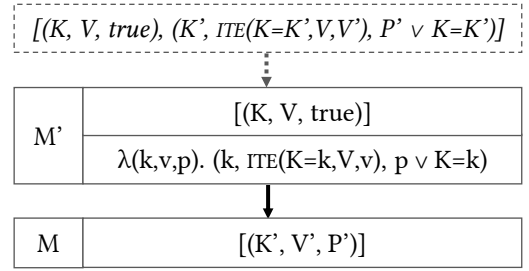

Figure 4. Example of a *set* layer M' on top of a map M, and the resulting known items of M'.

The engine thus tracks a *condition* and a *value hint* during ghost map operations, which are set when handling invariants and used to stop recursion when handling *get*.

When handling a map invariant of the form $get(...) = ...$, the engine adds to the condition the presence bit given as argument to the invariant and sets the value hint to the value expected by the invariant. These changes are reverted when the engine is finished handling the invariant.

$get(M, K)$ needs two changes at the start: First, if K cannot be different from an existing item's key assuming the condition holds, return that item's value and presence bit. Second, after creating the fresh V, if there is a condition, add "the condition implies $V = value\_hint$" to the path constraint.

Applying this logic to our example solves the issue. When handling $get(M_2, V)$, the value hint is K and the condition is P, both from the newly-known item of M_1. When M_2's invariant calls $get(M_1, V')$, the path constraint contains $P \Rightarrow V' = K$, thus the *get* on M_1 will start by checking whether its known item (K, V, P)'s key is equal to V' assuming P, which it is, and return (V, P), ending the recursion.

This strategy avoids recursion in common cases such as our example of maps with reciprocal keys and values, but it is not complete, as the engine may recurse infinitely. For instance, "M_1 has $min(K - 1, 0)$ for all K in M_2, and M_2 has $min(K - 1, 0)$ for all K in M_1" could hold, but will lead to infinite recursion in the engine given our implementation.

We present the final *get* algorithm, which is the core of our ghost map technique, in Appendix B. Our technique is decidable and expressive but not complete, unlike prior work that focused on completeness at the expense of expressiveness [3, 13]. Our technique enables a symbolic execution engine to translate ghost map operations into formulas on quantifier-free bit vectors. This enables the engine to bypass the path explosion caused by data structure code by executing the code's contract instead.

The universal "forall" quantifier on ghost maps allows contracts even for operations that cannot be implemented using maps by describing *what* they do instead of *how*. However, we believe some data structures are not a good fit for ghost maps, specifically ordered ones. While queues and stacks can be viewed as maps from indexes to elements, the resulting contracts are unlikely to be conducive to invariant inference.

4 Invariant inference

Handling data structures by translating them to ghost maps is not sufficient for automated verification. Developers use data structures in well-defined patterns, named *invariants*, but these patterns are not always explicit in the code.

Verification tools must *infer* such invariants to avoid failures. When executing a contract instead of an implementation, the tool must have enough information to prove the contract's precondition. Previous tools bypassed this problem by special-casing data structures and their invariants.

The ghost maps representation we proposed in §3 enables tools to infer invariants without special-casing templates.

Consider these motivating examples in pseudo-code:

```
if packet.flow in table:
    statistics.increment(packet.flow)
```

If `increment`'s contract requires the item to be in `statistics`, symbolic execution will fail if it cannot prove this fact.

```
device = destinations.get(packet.flow)
transmit_packet(packet, device)
```

If `transmit_packet`'s contract requires the device to exist, symbolic execution will fail if it cannot prove this fact.

```
if not items.full:
    items.add(x)
    metadata.add(x, y)
```

If `add`'s contract requires free space, symbolic execution will fail if it cannot prove `not` `metadata.full` in the second `add` call.

All three examples could be bugs depending on how the data structures they deal with are updated. If the first example is in code that always adds `packet.flow` to both `statistics` and `table`, the code is valid. If the second example always puts a device known to be valid in `devices`, such as the incoming device of a packet, the code is valid. If the third example is the only occurrence of `add` in the code and both structures have the same length, the code is valid.

To infer invariants, our algorithm starts from the strongest possible ones then iterates by relaxing them as needed until it finds a fixed point, as we illustrate in Algorithm 2. The starting point is the program states resulting from symbolically executing the network function's initialization code. At this point, the invariants are the strongest possible ones: "all maps will always be exactly as they are after initialization".

---

function FindFixedPoint(*code*)
  invs = *InitialInvariants*(*code*)
  states = *InitialStates*(*code*)
  do
    invs = *Relax*(*invs*, *states*)
    states = *SymbolicallyExecute*(*states*, *invs*)
  while *invs* do not hold on *states*
  return *invs*

Algorithm 2: Core of the invariant inference algorithm.

The initial invariants are unlikely to hold on the packet processing code, unless the code does nothing. After symbolically executing the packet processing code for one iteration of the network function's infinite packet-processing loop, the engine *relaxes* the invariants to match the program states that result from the iteration. For instance, the initial invariant "the firewall's `flow_table` is always empty" could be relaxed into "the `flow_table` may have items, and its length is always the same as the `statistics`". The engine then symbolically executes a packet-processing iteration again using these new invariants, which may lead the engine to explore new paths in the code such as a path in which the packet's flow is found in the `flow_table`, previously infeasible as the table was assumed to be empty. The engine then relaxes the invariants again, and executes an iteration with these new invariants, until the invariants no longer need relaxing after an iteration. By definition, the final relaxation yields invariants that hold on the initial state as well, thus the result is a correct set of invariants. The algorithm is guaranteed to converge since the set of invariants can only shrink. It may converge towards the empty set of invariants because the code has no invariants or because the engine could not infer any. The goal is not to find some "ideal" set of perfect invariants, only enough invariants to be able to symbolically execute and verify the code. If some properties happen to hold but are not necessary, inference need not find them.

The key to inferring useful invariants is to use ghost maps' *known* items to form invariant candidates, and then check whether these candidates hold using the *unknown* items. Thus, instead of using low-level invariant templates such as "the value is nonzero" as in Houdini [20], the tool can find invariants based on the constraints that hold on known items. For instance, the tool does not need a definition of a "device" to solve our second motivating example.

Besides finding invariants among map items and lengths, tools can also find invariants *across* maps. Such invariants are of the form "if M_1 associates key K with value V, then M_2 has some key and possibly value related to K, V". For instance, in the first motivating example, finding the invariant "all keys of `table` are also keys in `statistics`" enables the tool to prove that the code uses `increment` correctly. Inferring such invariants requires finding functions F_K, F_V, F_P for two maps M_1, M_2 such that $((get(M_1, K) = V) \land F_P(K, V)) \implies (get(M_2, F_K(K, V)) = F_V(K, V))$, or alternatively find only F_K, F_P and merely infer that M_2 contains $F_K(K, V)$ without inferring the associated value. Candidates for F_* are found using the known items and confirmed using the unknown items invariant.

In summary, the representation we propose for ghost maps also enables an elegant invariant inference algorithm based on finding candidate invariants and relaxing them as necessary. Representing known items explicitly lets a verification tool find useful candidates for invariants, instead of limiting itself to special-cased low-level templates.

5   Implementation

We implement our technique in KLINT, a tool which uses the angr [48] symbolic execution engine and the Z3 [12] solver.

KLINT takes a network function binary and a Python specification as inputs and proves that the binary satisfies the specification or produces a counter-example. KLINT can also be used without a specification to check that no path in the code crashes or accesses memory out of bounds.

KLINT first identifies all environment interactions in the binary, which correspond to data structure operations or networking operations, using the symbols that the binary must export since it dynamically links the environment code. Then, KLINT maps these operations to their contracts, provided by the developers of the data structures and of the networking environment. Data structure contracts are written in terms of ghost maps, as defined in §3, while the handful of fundamental networking operations such as transmitting a packet have manually written contracts for KLINT. When the binary calls its environment, KLINT symbolically executes the corresponding contract instead of the implementation, inferring types and control flow information as described in §2.2: KLINT knows the types of parameters to environment interactions, and extracts control flow in the form of path constraints. This enables KLINT to understand the semantics of the binary under verification in terms of its environment.

KLINT symbolically executes the network function's initialization code, as defined in §2.1, then infers invariants that hold in all packet-processing paths by symbolically executing the packet-processing code until it finds a fixed point, as described in §4. KLINT then checks whether all packet-processing paths satisfy the specification, which indicates whether the network function binary as a whole does.

Specifications are Python programs that use ghost maps, which KLINT interprets using peer symbolic execution [6] on each state resulting from symbolic execution of the binary. The binary may abstractly manipulate more than one ghost map, since it may use multiple data structures and individual data structures may be modeled by contracts as multiple maps. Thus, when the specification refers to a map, KLINT must infer which of the maps it is, using heuristics to try likely candidates first, and only fail verification if the specification is violated for all possibilities. For instance, a firewall can track outgoing flows and maintain statistics per IP address. KLINT must infer that the flow table in Algorithm 1 is the abstract form of the former data structure, not the latter.

Developers must comply with good programming practices such as state separation if they want verification to succeed, and KLINT enforces this during verification. If developers do not separate data structure code from the rest of the network function, KLINT will encounter too many paths and fail once it has executed a configurable instruction threshold. Developers already follow even stricter practices to write BPF programs due to the strict Linux verifier [10].

KLINT models heap memory with ghost maps, treating memory as just another kind of data structure and including it in invariant inference. Developers use a standard calloc-like interface to allocate memory. During symbolic execution, memory allocations return *symbolic pointers*, ensuring that KLINT will explore all paths even if some paths depend on the value of pointers. This is not the case in a tool such as Vigor [53], which uses concrete pointers.

To ensure that developers cannot "hide" memory from KLINT, all memory outside of the stack and the maps-modeled heap is read-only after initialization. This is not a limitation on sensible developers, who allocate on the heap through the environment and cleanly separate mutable state.

Our memory model is similar to Memsight [9] and KLEE's segmented memory [26], but it requires almost no effort to implement thanks to the flexibility of ghost maps.

KLINT can do *full-stack* verification, verifying the entire software stack, including the network driver and most of a minimal operating system.

To verify the network driver, KLINT matches hardware accesses to the *actions* they correspond to, using a hardware description of the network card written in a domain-specific language and based on publicly available data. KLINT intercepts reads and writes to network card registers, which usually go through port- or memory-mapped I/O. When the network driver writes a value to a register, KLINT reverse-engineers what the driver might be doing by finding all actions that could match the write, and checking which ones are feasible in the current hardware state. For instance, if the driver sets the "enable promiscuous mode" flag in the network card, KLINT looks up the corresponding action and checks its precondition, which states packet reception must be disabled. If the precondition does not hold, or if no action matches the write performed by hardware, KLINT aborts verification. Actions can also have postconditions describing what happens to the hardware as the result of an action, such as a self-clearing bit in a register.

The only environment operations for which KLINT uses contracts instead of implementations during full-stack verification are the data structures and the memory allocator due to their complexity. We verified that they obey their contracts using machine-checked proofs.

Full-stack binary verification does impose one constraint: while the network function and its network driver can be compiled together, the environment has to be compiled separately and then linked together without link-time optimizations, ensuring the symbols corresponding to environment operations exist and can be given as an input to KLINT.

Our trusted computing base is made up of KLINT itself, including angr and Z3; the bootloader; the hardware; and the VeriFast [25] theorem prover we use to verify the memory allocator and data structures. Since VeriFast verifies source code, we trust the C compiler for the data structures and memory allocator, but this is not a fundamental limitation.

6 Evaluation

We evaluate KLINT using the binaries, without debug symbols, of 6 network functions: an Ethernet bridge with a spanning tree protocol, a firewall, an implementation of Google's Maglev [16], a network address translator, a traffic policer, and an IPv4 router with longest prefix matching. The first five are based on publicly available code from the Vigor [53] project, which verified source code.

We show that KLINT can quickly verify binaries in §6.1, that it reduces the trusted base and enables developers to write faster code in §6.2, and that it is applicable to real-world code including BPF in §6.3.

6.1 Verifying network functions

We summarize the time it takes KLINT to verify our network functions in Table 1, split into the time to symbolically execute the code, infer invariants, and verify the resulting paths. KLINT runs multiple iterations of symbolic execution and invariant inference to find a fixed point, thus we report the total time spent in each category.

We measure all times on an Intel i7-7700HQ CPU running at 3.60GHz. KLINT is single-threaded, though invariant inference is embarrassingly parallelizable. We prototyped parallelization but ran into a complex bug between angr and Z3 due to garbage collection [1], and since KLINT is fast enough we did not investigate further.

Overall, even the most complex of our network functions, the bridge, takes about 2 minutes to verify, which we believe is reasonable. We could further reduce verification time by reducing the redundancy in some invariants, and by using less flexible tools than angr and Z3, since we do not use their full power. The router uses a single data structure, the longest-prefix-match table, thus it only has one invariant.

We caution against over-interpreting the exact results, as most of the time is spent by the Z3 solver, and we noticed that the time Z3 takes to solve queries can vary significantly with small changes in queries, due to the heuristic-based nature of solving. Thus, total verification time can vary by dozens of seconds with minor changes in KLINT or Z3.

	Time (seconds)				#invs
	Sym. ex.	Inv. inf.	Verif.	Total	
Bridge	82	18	19	**119**	32
Firewall	26	7	10	**43**	20
Maglev	36	11	10	**57**	25
NAT	43	7	8	**58**	20
Policer	53	10	6	**69**	25
Router	0	0	1	**1**	1

Table 1. Our network functions, the time KLINT takes to verify them, and the number of invariants it finds.

```python
1  def spec(pkt, config, sent_pkt):
2    if pkt.ipv4 is None or pkt.tcpudp is None:
3      assert sent_pkt is None
4      return
5    if pkt.device == config["external device"]:
6      flow = {
7        'src_ip': pkt.ipv4.dst,
8        'dst_ip': pkt.ipv4.src,
9        'src_port': pkt.tcpudp.dst,
10       'dst_port': pkt.tcpudp.src,
11       'protocol': pkt.ipv4.protocol
12     }
13     # there must exist a map that tracks flows,
14     # regardless of what it maps them to
15     table = Map(typeof(flow), ...)
16     if sent_pkt is not None:
17       assert flow in table.old
18       assert sent_pkt.data == pkt.data
19       assert sent_pkt.device == 1 - pkt.device
```

Listing 2. Partial specification of a firewall with 2 devices. This specification can be given to KLINT unmodified.

We show the KLINT equivalent of Algorithm 1, our running example of a specification, in Listing 2. The full specification is too long to show here, but KLINT can also verify this partial specification.

The specification abstracts away implementation details such as the type of values in the firewall's flow table, as seen in line 15. This uses Python's "ellipsis" literal, meant for domain-specific languages.

This specification is actual Python code run in the standard Python interpreter by KLINT, thus developers can write specifications using their existing programming knowledge. KLINT currently requires the order of fields in specification structures such as the flow declared in line 6 to match the order in the corresponding implementation structure. Having KLINT try all possible orders would not finish in reasonable time, but there may be better strategies.

We found and fixed two implementation bugs using specifications we wrote based on standards. First, section 7.8 of the IEEE 802.1D standard [30] forbids adding Ethernet group addresses to the filtering table, which we originally forgot to implement. Second, our NAT originally misused its port allocator if configured to use only a sub-range of ports. This was already present in the Vigor NAT, because Vigor requires a concrete size for data structures during verification, and its authors only verified it for the full port range.

Verifying the entire stack requires an additional 15 minutes per network function, most of which is spent inferring the network driver's actions because the driver performs thousands of writes to registers and each of these writes requires work from KLINT. This could be improved by recognizing simple loops, since most initialization operations are performed in loops over categories of registers.

6.2 Faster verified network functions

KLINT enables developers to write faster verified network functions in two ways: developers can quickly prototype changes to data structures without having to verify them first, and they can use the abstractions they want instead of verification-specific ones. In practice, we expect developers to either use existing verified data structures or write contracts for existing "trusted" data structures such as BPF maps. KLINT enables this workflow by only requiring contracts and not proofs for these trusted data structures, whereas previous tools required an all-or-nothing approach.

First, ghost maps and invariant inference enable quick prototyping of new data structures. For instance, we rewrote our port allocator to have different performance characteristics with slightly different semantics, including stricter preconditions as we believed our network functions did not need the generality of the existing ones. Using an approach such as Vigor or Gravel, even when prototyping, we would have needed to add a model of the new port allocator to the verification tool, including annotations for invariants, to check whether our network functions would still be correct when using it. With KLINT, we wrote new contracts, automatically verified that our network functions already satisfied the new stricter preconditions, then manually verified the implementation once we finished prototyping.

Second, verifying binaries enables simpler and faster code by removing abstractions over low-level hardware features that existed for the sake of verification. For instance, using a tool such as Vigor, obtaining the time from the environment requires calling a C function that the tool replaces with a model at verification time. Unless the compiler can inline this function, the developer will pay the performance cost at run time. With KLINT, the code can use inline assembly to read the CPU's time stamp counter, which KLINT handles in the same way as other assembly instructions. Furthermore, in the Vigor model, the C function must be verified separately using a different tool, a problem KLINT does not have.

	Vigor			KLINT		
	Tput	**Latency** (*us*)		**Tput**	**Latency** (*us*)	
	(*Gb/s*)	50%	99%	(*Gb/s*)	50%	99%
Bridge	5.54	3.98	4.25	10*	3.84	4.26
Firewall	7.77	3.92	4.26	10*	3.84	4.25
Maglev	6.34	3.96	4.28	10*	3.90	4.27
NAT	3.47	3.97	4.32	10*	3.87	4.27
Policer	9.12	3.87	4.25	10*	3.83	4.24

Table 2. Maximal single-link throughput without loss, and latency with 1 Gb/s background load of the original Vigor network functions and our versions.   * = link saturated

Figure 5. Throughput without loss vs. median latency of different bridges. Shaded areas delimit 5th and 95th percentiles.

We benchmark our network functions using the Vigor ones as baselines, with the TinyNF [45] driver instead of the original DPDK subset since it is faster and is the base for our own network driver. We use the same setup as Vigor to make the comparison useful: two machines as in RFC 2544 [4], one running a network function and one running the MoonGen packet generator [17]. Both machines have Intel Xeon E5-2667 v2 CPUs at 3.30GHz, Intel 82599ES NICs, and run Ubuntu 18.04. These network cards are the ones we modeled for KLINT's full-stack verification. We measure throughput with minimally-sized packets, filling network functions' flow tables to 90% of their capacity.

We first run the same benchmark used in the Vigor paper: find the maximum throughput the network functions can sustain without dropping packets using one 10 Gb/s link and measure their latency when fed 1 Gb/s of background load. All our network functions can handle 10 Gb/s whereas the Vigor ones cannot, as we show in Table 2.

Since the Ethernet link is a bottleneck in the Vigor benchmarks, we use two links, for a theoretical maximal throughput of 20 Gb/s. To obtain more details about performance, we measure latency at increments of 1 Gb/s until the network function drops packets. We focus on the bridge for lack of space. We included the original Vigor bridge running on its verified DPDK subset, the Vigor bridge running on the verified TinyNF driver, the Click [28] bridge originally used as a baseline by Vigor, our bridge running on our verified driver, and our bridge running on DPDK, which is not verified. We do not know of any "standard" network functions we could use as a baseline beyond Click.

Despite our bridge having extra features compared to the Vigor one, such as support for a spanning tree protocol, it can reach more throughput before dropping packets than any of the other bridges, including the bridge from the widely used Click toolchain, as we show in Figure 5.

	Language	Data structures	Extra inputs	Pointer arith.	Unbounded loops	Precise
Gravel [55]	LLVM	C++ STL	Intermediate specs	Limited	No	Yes
Prevail [21]	BPF	BPF maps	No need	If safe	Yes	No
Vigor [53]	LLVM	Custom "libVig"	NF-specific models	No	No	Yes
KLINT	x86_64	Any, w/ contracts	No need	If safe	No	Yes

Table 3. Comparison of this work with previous network function verification efforts.

6.3 Applicability

KLINT is applicable to real-world network functions: it does not require additional inputs from developers, it enables operators to verify the entire stack of network functions, its network function model is a superset of the widely used BPF, and it enables developers to use any programming language including those not considered mature enough to be trusted.

As we show in Table 3, KLINT operates on binaries, can handle any data structure for which map-based contracts are provided, does not require intermediate inputs, does not limit developers' use of pointer arithmetic beyond memory safety, and precisely tracks the contents of data structures and packets enabling functional correctness proofs.

Previous work falls into two categories. Vigor and Gravel prove functional correctness but require a typed intermediate language, extra inputs, and specific data structures. Prevail [21] handles BPF bytecode and maps, which BPF developers must use anyway, and can even handle unbounded loops, but can only prove memory safety and crash freedom. Prevail can be viewed as a superset of the Linux BPF verifier. KLINT provides the best of both worlds: it requires neither a typed intermediate representation nor extra inputs, and it does not limit data structures, while also enabling proofs of functional correctness. As an example of unnecessary inputs, we were able to remove around 3000 lines of proofs for invariants when porting Vigor network functions to KLINT.

Operators can verify the entire software stack, and thus do not need to trust software such as network drivers, using KLINT's full-stack verification. Developers can thus tune the drivers for performance by removing features they do not need, or even rewrite their own driver to suit it to a specific usage pattern. PacketMill [19] showed that such transformations can be done with developer hints to increase network function performance.

KLINT can be used to verify network functions in containers, i.e., statically linked with a Linux implementation of the environment abstraction and running within Docker [34]. Containers are a convenient way to deploy and manage programs and have been proposed as a deployment model for network functions [50]. KLINT can verify such network functions in the same way it verifies full-stack ones, although the trusted code base is larger since operators need to trust the container runtime as well as the Linux environment implementation running inside the container.

Our network function model is a superset of BPF. The Linux kernel verifies that BPF programs are memory safe and have no unbounded loops. KLINT verifies functional correctness, though it also requires a lack of unbounded loops. BPF requires developers to use a fixed set of data structures, mostly maps. KLINT enables developers to use any data structure that has contracts based on ghost maps.

To show that KLINT's model is at least as expressive as BPF's, we use five existing BPF programs: Facebook's Katran [47] load balancer, the CRAB [27] load balancer, a filter from Suricata [44], a firewall from hXDP [5], and a bridge from Polycube [35]. We extend KLINT to analyze the assembly code compiled by the kernel after dumping it through a Linux debugging facility, using contracts we wrote for the BPF maps. Since we have no specifications for these BPF programs, KLINT only verifies memory safety and crash freedom. KLINT verifies the bridge and firewall in seconds, and CRAB and the Suricata filter in less than 2 minutes, but Katran requires almost 4 hours. This is due to our choice to model packet contents with a ghost map for simplicity, even though packet contents do not factor into invariant inference. Katran reads and writes to dozens of fields in the packet, which means the ghost map representing the packet has too many items to be efficient. This could be fixed by using a different way to model packet memory, such as Z3 arrays.

Developers can use any programming language, even if that language is considered too "exotic" or "immature" for operators to blindly trust it, since KLINT verifies binaries, and thus can catch errors resulting from compiler bugs.

For instance, the Rust [39] programming language is a promising direction for writing low-level systems code, including networking, but a developer or an operator might be concerned about its maturity level. Indeed, as of this writing there are currently 69 issues in the Rust bug tracker [46] marked with the "unsound" tag, meaning the compiler allows code that violates Rust's safety guarantees. Furthermore, some Rust features such as removing unused parts of the standard library are currently experimental.

However, we are able to write a traffic policer in Rust, compile it using these experimental features, and verify it using KLINT with the same specification as our C implementation. We can thus be confident that no matter what bugs lie in the Rust compiler, our binary is correct.

7 Limitations

KLINT's main limitation is that it cannot handle multi-threaded network functions that share state across threads. As we stated in §2, parallel code causes path explosion due to the amount of possible interleavings among threads. Running isolated instances of a network function in parallel can work by steering flows to cores, in which case KLINT can verify the instances, but this has skew issues.

KLINT imposes the following performance limitation on network functions: data structures must be dynamically linked so that KLINT can identify their operations by mapping the symbols left undefined in the binary to the contracts it is given as inputs. This can lead to slower function calls and lost opportunities for inlining.

KLINT also has the non-fundamental limitation of only supporting packet arrival as a trigger to run code and not timers or other events. Extending KLINT to support this is engineering work, replacing the restricted event handler model of packet reception with a more general one that branches on the event type.

Verifying network functions is only one part of the puzzle. KLINT can verify that a network function implements a protocol, but not that the protocol itself satisfies properties such as avoiding infinite message loops. Specialized techniques exist to verify protocols, such as IronFleet [22].

The remaining part of the puzzle is data structure implementations, for which manual verification tools currently remain necessary. We used VeriFast [25], which uses annotation for C, but other approaches exist such as Dafny [31], a programming language designed for verification.

8 Related work

Runtime verification is a related but distinct area of work, focusing on checking behavior at runtime. This catches bugs even in code currently beyond the reach of formal verification, for instance due to complex parallelism. Tools such as Aragog [52] trade completeness and performance for applicability. They only look at input and output packets and view network functions as "black boxes", thus they impose no constraints on code. But they cannot guarantee the absence of bugs, and in distributed environments cannot prevent bugs that can only be detected after compiling information from different machines. They also impose runtime overheads, unlike KLINT, due to the runtime nature of checks.

Symbolic execution is the main technique we build upon, and ghost maps may be useful beyond network functions. Symbolic execution is often used for bug finding instead of verification because of path explosion, but it can be augmented with techniques to bypass path explosion. Indeed, KLEE [7] and angr [48] were both designed primarily to find bugs, yet Vigor [53] and KLINT show that they can be used for verification. S2E [8] was also designed to find bugs but reused for network function verification by Dobrescu

and Argyraki [14]. Serval [40] is a symbolic execution engine enhanced with verification techniques and can prove systems such as a security monitor, at the cost of requiring some human annotations. KLINT could have used Serval as a base; we chose angr mostly because it is designed for quick prototyping. Path explosion can also be bypassed by writing code with few paths, as in the Hyperkernel [42].

Using maps as part of analyzing programs has been proposed before, though previous approaches were not aimed at functional verification, such as the Memsight [9] memory model for symbolic execution, or the technique proposed by Dillig et al. [13] to verify memory safety.

Network function verification tools such as Vigor [53], Gravel [55], and Prevail [21], which require source code, all inspired our design. Bolt [24] and Pix [23] verify performance instead of correctness, and require source code, though we believe they could use our techniques to only require binaries. While verifying binaries provides key advantages, verifying source code makes debugging failed verification easier since compiler optimizations can make it hard to match what the binary does wrong to what the code does wrong.

BPF is a more applicable but weaker form of network function verification: an in-kernel "verifier" checks memory safety and crash freedom, allowing untrusted code to run in kernel mode for performance without safety risks. BPF verifiers are fast, at the cost of restricting the code developers may write. BPF code cannot contain unbounded loops, must use specific data structures, and must include explicit checks for out-of-bounds memory accesses, even if a "smarter" and slower verifier might not need these checks. Internet infrastructure companies such as Cloudflare [32] use BPF as a core part of their infrastructure. Prevail [21] showed that formal methods can help BPF verification scale. Verified interpreters [51] and just-in-time compilers [41] for BPF exist, but they make no promises about functional correctness.

9 Conclusion

We presented KLINT, an automated tool to formally verify that network function binaries satisfy specifications with neither source code nor debugging symbols, given contracts for trusted data structures. This enables developers to provide guarantees about proprietary code to operators, removing a key barrier for adoption of formally verified network functions. KLINT uses maps as "universal" data structures for both specifications and contracts, enabling a sweeping simplification in reasoning including invariant inference. Using KLINT, we verified the functional correctness of 6 network function binaries written in C and 1 in Rust, and the memory safety and crash freedom of 5 existing BPF programs.

Appendix A Verified properties

We used Klint to verify both network functions we wrote and existing BPF network functions. We summarize the properties we proved for our network functions in this appendix. The BPF network functions have no formal specification and writing one would require a discussion with their authors to understand which edge cases are intended and which are not, so we instead chose to only verify that they are memory safe and free of crashes.

The full specifications are available on our repository: https://github.com/dslab-epfl/klint.

Bridge: we wrote a specification by manually extracting properties from the IEEE 802.1D [30] standard. For instance, section 7.7.1 of the standard, "Active topology enforcement", states that "Each Port is selected as a potential transmission Port if, and only if [...] The Port considered for transmission is not the Port on which the frame was received [...]", thus our specification checks that if the packet was transmitted, the transmission port must not be the reception port. As we explain in Section 6.1, we found a bug after translating section 7.8 of the standard, "The Learning Process", which states a condition for learning an address in the filtering database: "the source address field of the frame denotes a specific end station (i.e., is not a group address)".

Klint helps us write this specification by allowing us to write properties that must hold on packets and on state without having to explicitly depend on the bridge's internals. For instance, we do not need to specify the data type that the bridge uses to store metadata about Ethernet addresses, only that the bridge conceptually has a map with Ethernet addresses as keys, and that the source address of an incoming packet is or is not added depending on specification-related factors.

Firewall: beyond the partial specification of Listing 2, we wrote a full specification that is an evolution of the one from Vigor [53]. We model the firewall's state as a map from flows to last update time and ensure that the firewall (1) adds flows from the internal network to the state if possible, refreshing their last update time if necessary, and (2) only lets packets from the external network through if their flow belongs to the state. The specification also ensures that the firewall does not modify packet contents and does not drop packets unless they are incoming packets with no matching flow in the state.

Our specification is not concerned with how the firewall "remembers" flows, nor with when exactly this happens in packet processing, only that outgoing packets flows must be remembered if there is space and that incoming packets must be of a known flow if they are forwarded.

As we show in §6.1, Klint can also verify a more restricted specification that is only concerned with what happens when a packet is transmitted, including the fact that its flow must have been known previously.

Maglev: while we do not know of a formal specification for Maglev, our specification is an evolution of the one from Vigor [53], which was written according to the behavior described by the Google paper [16]. We model the state as two maps, one from flows to backends and one from backends to last heartbeat time. Packets from backends are heartbeats and must update the corresponding last heartbeat time and then be dropped. Packets from clients must be routed to a backend and must not be dropped unless there are no available backends.

NAT: our specification is an evolution of the one from VigNAT [54], which fully describes the behavior of the NAT. We model the state as a map from flows to last update time, in a similar fashion to the firewall specification. Packets must only be dropped if they are not IP or TCP/UDP, as the NAT does not support other protocols (for now), or if they come from the external network but do not belong to a known flow. Packet headers must be updated according to the state, and packets from the internal network must trigger state updates.

One interesting aspect of Klint with regards to the NAT is invariant inference: Vigor's original NAT required about 3000 lines of manually written proof annotations for the invariants between the three data structures the NAT uses internally, and the Vigor specification was dependent on

these data structures. KLINT instead infers these invariants automatically, and our specification defines the NAT in terms of maps.

Policer: our specification is an evolution of the one from Vigor [53], which fully describes the behavior of the policer. We model the state as one map from buckets to tokens, and one map from IP addresses to buckets. The specification then enforces that the policer must update the state according to incoming packets and their size and drop packets if their bucket is too full.

Router: we wrote a specification based on RFC 1812 [43], "Requirements for IP Version 4 Routers". We model the state as a map from CIDR blocks to devices. We enforce the header validation requirements from section 5.2.2 of the RFC, the time to live requirements from section 4.9.9.2, and most importantly the longest-prefix-match property to find the next hop address from section 5.2.4.3.

Appendix B   Ghost maps *get* algorithm

We present here the algorithm for the *get* operation on ghost maps. PC is the Path Constraint. UK_M, UV_M, and UP_M are the triple forming map M's unknown item, as we explain in §3.3. The *condition* and *value_hint* are those required to handle invariant recursion, as we explain in §3.4.

function KnownSize(M)
    $result = 0$, $known = \emptyset$
    for (k, v, p) in M's *known items* **do**
       $result \mathrel{+}= ITE(k \notin known \wedge p, 1, 0)$
       $known \mathrel{+}= k$
    return $result$

function Get(M, K)
    for (k, v, p) in M's *known items* **do**
       if *unsatisfiable*$(condition \wedge K \neq k)$ **then**
          return (v, p)
    if *unsatisfiable*$(condition \wedge K \neq UK_M)$ **then**
       return (UV_M, UP_M)
    Let (V, P) be a fresh value and presence bit
    if *condition* is set **then**
       Add *condition* $\Rightarrow V = value\_hint$ to the PC
    Let $U = \bigwedge (K \neq K')$ for each known key K' in M
    Add (K, V, P) to M's known items
    for (k, v, p) in M's *items* **do**
       Add $K = k \Rightarrow \big((V = v) \wedge (P = p)\big)$ to the PC
    Add $U \Rightarrow invariant_M(K, V, P)$ to the PC
    Add $KnownSize(M) \leq length(M)$ to the PC
    return (V, P)

Differential Network Analysis

Abstract

Networks are constantly changing. To avoid outages, operators need to know whether prospective changes in a network's control plane will cause undesired changes in end-to-end forwarding behavior. For example, which pairs of end hosts are reachable before a configuration change but unreachable after the change? Control plane verifiers are ill-suited for answering such questions because they operate on a single snapshot to check its "compliance" with "explicitly specified" properties, instead of quantifying the "differences" in "affected" end-to-end forwarding behaviors. We argue for a new control plane analysis paradigm that makes differences first class citizens. Differential Network Analysis (DNA) takes control plane changes, incrementally computes control and data plane state, and outputs consequent differences in end-to-end behavior. We break the computation into three stages—control plane simulation, data plane modeling, and property checking—and leverage differential dataflow programming frameworks, incremental data plane verification, and customized graph algorithms, respectively, to make each stage incremental. Evaluations using both real and synthetic control plane changes demonstrate that DNA can compute the resulting differences in reachability in a few seconds—up to 3 orders of magnitude faster than state-of-the-art control plane verifiers.

1 Introduction

Networks are frequently in flux. Configurations are modified monthly, or even weekly: e.g., two large universities change up to 55 stanzas per router per month [27], and Facebook conducts an average of 12.5 changes per device per week in their backbone [41]. External peers update routes daily: e.g., four tier-1 ISPs each experience a median of ∼100K route updates per day [12]. Links and routers fail intermittently: e.g., a large online service provider's data centers have a median of 18.5 link outages per day [17], and the CENIC research network has a median of 38.5 outages per link per year [42].

Each change poses a risk of introducing catastrophic network outages [28, 31, 46]. To avoid outages, operators need

to know whether prospective changes in the control plane (i.e., changes in configurations, external routes, or available links/routers) will cause (un)desired changes in end-to-end forwarding behavior. For example, would a link failure break isolation? Would a configuration change reduce reachability? Would an external route withdrawal degrade load balancing?

At first glance, existing verifiers [1, 4, 6, 7, 13–15, 18, 22–24, 26, 33, 37, 40, 43, 45, 48] seem to address this need. However, data plane verifiers [18, 19, 23, 24, 26, 33, 44, 48] cannot directly answer these questions, because they operate on changes in the control plane's output, rather than the control plane itself. Existing control plane verifiers [1, 4, 6, 7, 13–15, 22, 37, 40, 43, 45] are also ill-suited for this task, because of the following limitations: (1) they focus on checking a single control plane snapshot instead of differences between snapshots and (2) they require a list of properties to check, but it is difficult for operators to determine which properties may be affected by a change and hence need to be checked.

For the first limitation, a possible workaround is to apply a control plane verifier to both the old and new snapshots and compare the verifier's output. But analyzing both snapshots from scratch is wasteful, because many control plane changes have a limited impact on the data plane. For example, fewer than 100 forwarding (ACL) rules are changed for >80% (>90%) of configuration changes in the backbone network at a large university (Figure 1), and Steffen et al.'s experiments with 90 ISP topologies show that only one-third of link failures impact the forwarding path between a randomly chosen ingress node and destination prefix [40].

For the second limitation, a possible workaround is to check reachability (or other properties) for all pairs of end hosts. But checking all possible properties is wasteful, because the space of all properties is large [9] and the set of properties affected by a change is often small. Policy-mining tools [8, 9, 25] can help narrow the space of properties, but the set of inferred properties may still be large—e.g., Config2Spec returns over 3K properties for a national research and education (R&E) network with only 10 routers [9].

Since control plane verifiers can be quite inefficient for

assessing whether control plane changes cause changes in end-to-end behavior, we argue for a new control plane analysis paradigm which makes differences first class citizens. *Differential Network Analysis (DNA)* takes as input differences in configurations, external routes, and available links/routers, incrementally computes control and data plane state, and outputs the consequent differences in end-to-end behavior (e.g., reachability, waypointing, load balancing, etc.). This aligns with the small size/impact of many control plane changes and avoids duplicate and unnecessary computations.

To incrementally compute differences in forwarding behavior based on differences in the control plane, DNA breaks the computation into three modular stages—control plane simulation, data plane modeling, and property checking—and makes each stage "differential". In other words, each stage consumes differences (control plane changes, data plane changes, and forwarding graph changes, respectively), incrementally updates its network model, and produces differences (data plane changes, forwarding graph changes, and property changes, respectively). To achieve incremental computation for each of these stage, DNA leverages differential dataflow programming frameworks [2, 35], incremental data plane verification [48], and customized graph algorithms, respectively.

We implement a version of DNA that supports differential analysis of two widely-used routing protocols (BGP and OSPF) and widely important properties (reachability, waypointing, and load balancing). Our implementation of DNA is publicly released under an open source license. We evaluate DNA using both synthetic and real control plane changes, and demonstrate that DNA can compute differences in reachability induced by control plane changes in a few second—up to 3 orders of magnitude faster than state-of-the-art control plane verifiers [1,4,6]. Second-level verification time can enable on-the-fly checking of operator-proposed configuration changes, similar to syntax checkers integrated into most programming IDEs, as well as quickly validating automatically-generated changes due to dynamic control [30].

In summary, we make the following three contributions:

- We propose differential network analysis (DNA), a new paradigm that helps operators better understand the impact of changes in the control plane.
- We design and implement DNA based on recent advances in differential dataflow programming and incremental data plane verification, and apply optimizations to overcome their inefficiencies.
- We use both synthetic and real control plane changes to show DNA computes consequent differences in end-to-end behavior up to 3 orders of magnitude faster than state-of-the-art control plane verifiers [1,4,6].

2 Motivation

In this section, we discuss in detail why invoking a control plane verifier before and after a change, and for all inferred

Figure 1: The number of changed (forwarding and ACL) rules, and the number of changed configuration lines for the backbone network at a large university.

properties, is an inefficient way to assess whether changes in the control plane cause changes in end-to-end behavior. In particular, we highlight: (1) the prevalence of small control plane changes, and (2) the difficulty of identifying which properties may be impacted by a change.

2.1 Control plane changes are often small

Control plane verifiers operate on full snapshots of the control plane, but the delta between snapshots is often small, which leads to significant amounts of unnecessary re-computation.

Configuration changes. Several prior studies have examined router configurations across various organizations/networks and found that changes are often small: e.g., two large universities each change (on average) ≤ 20 lines of configuration at the same time [36]; changes in Facebook's backbone and data center networks impact an average of 157 and 738 lines of configuration, respectively, which is relatively small compared to the scale of these networks [41]; and in 75% of the networks operated by a large online service provider, the median change includes only three devices [16]. Consequently, we expect control plane verifiers' inputs and outputs to be similar before and after such changes.

To validate this hypothesis, we analyze 3 months of configuration changes from the backbone network at a large university [36]. The network has 28 routers and 50 links and runs OSPF. On average, the network has ∼75K total lines of configuration, which generate ∼25K total forwarding rules. The configuration changes include adding/removing subnets, access control lists (ACLs), OSPF routes, etc. Figure 1 depicts the size of each configuration change and the corresponding number of changes in forwarding rules and ACL rules. On average, 228 lines of configuration (∼0.3%) are changed, causing 146 forwarding rules (∼0.6%) and 34 ACL rules (∼0.9%) to change. Except for two updates, all configuration changes result in <600 changes in forwarding rules.

External route changes. Prior studies have shown that autonomous systems (ASes) may experience a high rate of BGP updates—e.g., four tier-1 ISPs each experience a median of ∼100K route updates per day [12]—yet only 1% (10%) of next-hops in the Internet change each day (month) [10]. Con-

sequently, we expect external route changes to have a small impact on a network's control and data planes.

To validate this hypothesis, we analyze 1 year of hourly RIB snapshots from a national R&E network [3]. We exclude hours in which a configuration change was made to ensure we only capture RIB changes caused by external route changes. We find <15% of hours have at least one RIB entry change, and <4% of hours have more than 10 RIB entries change.

Link/router availability changes. Link/router failures—caused by software upgrades, hardware faults, etc.—are common: e.g., the CENIC Digital California and High Performance Research networks experience a median of 5.1 and 38.5 failures per link per year, respectively [42], and tens of geographically distributed data centers operated by a large online service provider experience a median of 18.5 link failures and 3 device failures per day [17]. However, Steffen et al.'s experiments with 90 ISP topologies showed that for a randomly chosen ingress node and destination prefix, two-thirds of link failures do not impact the forwarding path from the ingress to the destination [40]. In other words, we expect only a fraction of FIB entries to change when links/routers fail.

2.2 Identifying behaviors to (re-)verify is hard

Identifying how changes in the control plane impact end-to-end forwarding behavior is important for assessing whether the changes: (1) have the intended effect, and (2) have any undesirable side-effects.

For the former, it is easy to identify which behaviors to examine, because these behaviors are effectively the "design requirements" for the change. For example, operators may propose a change in filters to restrict access to a new subnet; the effectiveness of the change can be assessed by examining reachability between the restricted and new subnet(s).

In contrast, it is difficult to identify which behaviors should be examined to determine whether a change is "safe." Some behaviors may be obvious, because they relate directly to the change: e.g., to assess the safety of the proposed change in route filters, operators should examine reachability from non-restricted subnets to the new subnet. However, a change can also impact seemingly unrelated behaviors—e.g., reachability from non-restricted subnets to existing subnets—or behaviors outside of an operator's purview—e.g., changes in a single data center may affect how a WAN load balances traffic across multiple data centers. The latter can arise especially when different teams manage different aspects of a network, networks are merged (e.g., due to an acquisition), or operators with historical knowledge of the network leave an organization.

A simple way to ensure a change does not negatively impact seemingly unrelated behaviors is to examine all categories of end-to-end behaviors for all (pairs of) prefixes. However, this is prohibitively expensive [9], and likely results in lots of unnecessary computation—e.g., if access from a subnet was already restricted, then further restrictions in access are unlikely to impact reachability. Ideally, only behaviors that could potentially be impacted should be examined.

In summary, repeatedly analyzing full snapshots of the control plane is wasteful, and determining which end-to-end behaviors to analyze is hard.

3 Overview

This section overviews DNA, a modular network analysis framework which can incrementally compute the "differences" in forwarding behavior that arise from "differences" in the control plane. We will first present the framework of DNA, and use an example to show its workflow. After that, we discuss three challenges when realizing DNA.

3.1 The DNA workflow

DNA is a modular framework with three stages, where each stage consumes and produces some forms of *differences*.
- The first stage consumes control plane changes and simulates the control plane to generate differences in data plane state (i.e., insertions/deletions of forwarding rules).
- The second stage updates a data plane model to generate differences in forwarding graphs (i.e., insertions/deletions of packet equivalence classes on edges).
- The third stage identifies and checks relevant end-to-end forwarding behaviors to generate differences in end-to-end properties (e.g., changes in reachability).

We use an example to show how these three stages work.

An example network. Figure 2(a) shows an example network which is used throughout the paper. The network has five routers running BGP. Router E announces two /24 prefixes and one /16 prefix. There is an outbound route filter at port 2 of router E, which filters routes for the /16 prefix, and an inbound ACL at port 2 of router D, which drops all traffic to the two /24 prefixes. The green and yellow arrows represent the best routes selected at each router.

To simulate a change, we consider a single link failure, i.e., the link between router C and E fails. As a result, router A can no longer reach the two /24 networks. We show how DNA can uncover this change in reachability.

Stage 1. Differential control plane simulation (§4). This stage takes as input differences in control plane state, incrementally simulates the control plane, and outputs differences in data plane state. Differences in control plane state are insertions/deletions of configuration lines, external routes, or links/routers, and differences in data plane state are insertions/deletions of forwarding/ACL rules. Generally, simulating a control plane entails modeling the route propagation, filtering, and selection behaviors within and across distributed routing protocols to compute the converged control plane state and produce a concrete data plane [1, 7, 14, 34, 37, 38]. To be incremental, we must transition from one converged state to
Figure 2: An example demonstrating the workflow of DNA.

another, accounting for the impact of control plane changes on route propagation, filtering, and/or selection across routers.

In our example, the link failure between port 1 of C and port 2 of E will be encoded as a deletion of a record $Link(C, 1, E, 2)$, which is the input the Stage 1. Given this input, DNA simulates the control plane and generates FIB differences: e.g., at router C, the two /24 routes whose output port is 1 (2) are deleted (inserted), as shown Figure 2.

Stage 2. Differential data plane modeling (§5). This stage takes as input differences in data plane state, incrementally constructs a data plane model, and outputs differences in the data plane model. Generally, a data plane model partitions the packet space into *Equivalence Classes (ECs)*, each of which represents a set of packets with the same forwarding behavior through the network [26]. Then, the model concisely encodes the forwarding behavior of packets with a forwarding graph, where each edge is labelled with ECs that can traverse it [18, 48], as shown in Figure 2. When rules are inserted or deleted, ECs are split, merged, and transferred among edges, to reflect the forwarding behavior change.

In our example, there are three ECs in total, where a represents $[1.1.1.0, 1.1.2.255]$, b represents $[1.2.0.0, 1.2.255.255]$, and c represents all other IP addresses (which are not shown here). Since forwarding rules for the two /24 prefixes which output to port 1 are deleted, and those which output to port 2 are inserted, EC a "transfers" from edge (C, E) to edge (C, D) and from edge (B, C) to edge (B, D), as shown in Figure 2. Thus, the differences of data plane model consist of two insertions and two deletions for EC a on these four edges.

Stage 3. Differential property checking (§6). This stage takes as input differences in the data plane model (i.e., insertions and deletions of ECs on the forwarding graph), incrementally computes relevant forwarding behaviors, and outputs the differences in properties. Here, the differences in properties, which we term as *differential properties*, are defined as insertions and deletions of forwarding properties, including reachability, waypointing, load balancing, etc. DNA computes differential properties by traversing the forwarding graphs from edge ports, which are ports that connected to the hosts, servers, or other networks. The traversal starts with a set of all affected ECs, which are updated by intersecting with those ECs labelled on the edge. The traversal ends when the set of ECs becomes empty or another edge port is reached.

In our example, we have three edge ports, i.e., port 1 of A, B, and E. By traversing from these edge ports, we get the

differential reachability as $-Reach(A_1, E_1, a)$, meaning that packets belonging to EC a can no longer reach port 1 of E from port 1 of A. As will be shown in §6.2, DNA optimizes the above computation by traversing directly from the *change points*, where network forwarding behaviors change (B and C in this example). Note that network invariants like loop-freedom and blackhole-freedom are covered by differential reachability, since loops or blackholes will result in some pairs of end points becoming unreachable.

3.2 Challenges in realizing DNA

Realizing each of the three stages of DNA requires addressing the following three challenges, respectively.

(1) How to achieve control plane simulation in a way that is easy to extend? Network control plane has complex semantics, and simulating a control plane to cover all relevant feature often lead to complex code base. Generally, an incremental algorithm can be much more complex than its non-incremental counterpart [39]. Thus, incremental control plane simulation can be difficult to build. In addition, this is not a once-for-all task, considering the semantics of the control plane are still evolving, and new vendor-specific features emerge. Therefore, DNA needs to realize incremental control plane simulation in an easy-to-extend way.

(2) How to efficiently update data plane model for batched rule updates? Existing data plane verifiers are designed to consume single-rule updates—i.e., for each rule insertion or deletion, they individually update the model. For DNA, however, the differences in data plane state consist of a batch of rule updates. As an example, a link failure causes deletions of rules for multiple prefixes which are previously forwarded through the failed link. In such a setting, consuming single-rule updates can result in redundant computation, since these rule updates are often correlated. Therefore, DNA needs to optimize the data plane model update algorithm for batched rule updates.

(3) How to determine and only re-check affected properties? Existing data plane verifiers can incrementally check invariants like blackhole-freedom and loop-freedom by only re-verifying the ECs affected by a FIB update. DNA, however, needs to check all properties of some type (e.g., all-pairs reachability), and re-checking all these properties is wasteful since often only a small portion of the properties are affected. Therefore, DNA needs a way to determine which properties

are affected, which is not easy: e.g., it is unclear which reachability properties may be affected by a change in OSPF cost.

We describe how we address these challenges in §4–§6.

4 Differential Control Plane Simulation

As the first stage, DNA maps differences in configurations, external routes, and available links/routers to differences in FIBs. In the following, we show how DNA achieves this mapping in an incremental and easy-to-extend manner.

4.1 Modeling the control plane

A network control plane computes routes in a recursive way: each router receives routes from neighboring routers, filters and/or modifies the routes, locally ranks the routes to select the best routes, and advertises the best routes (which may be filtered/modified) to neighboring routers. The steps are repeated until routing converges—i.e., no more changes are made to any routing information bases (RIBs).

Leveraging differential dataflow for automatic differential computation. The aforementioned process fits well into the *dataflow* programming model. A dataflow program corresponds to a directed graph where vertices represent operators (i.e., functions that transform data), and edges represent the flow of data between operators [20]. For control planes, filtering, modifying, and selecting routes can be modeled with operators, and the propagation of routes between RIBs corresponds to the flow of data.

Differential Dataflow (DD) [35] is one dataflow programming framework which supports general incremental computation for recursive dataflows. This is achieved with a set of differential operators like `join`, `count`, etc. which efficiently produce differences in outputs from differences in inputs.

The left of Figure 3 shows a part of the dataflow program for OSPF route propagation using operators offered by DD. It `joins` the routes stored in a collection `BestOSPFRoute` with another collection `OSPFNeighbor` to model the propagation of routes from one router to another router; `filters` the routes where the origin of the route is the router itself (in order to prevent loops); `joins` with the collection `OSPFCost` to get the OSPF cost configured on the interface where the route is received; `maps` the routes to new routes with the OSPF cost updated by adding the interface's cost; and finally `joins` with `InterfaceIP` to get the IP of the interface to produce routes `OSPFRoute`, which will be further be processed to produce the `BestOSPFRoute` (omitted here).

Leveraging differential Datalog for better extensibility. As can be seen in the above example, modeling route computation directly using low-level operators offered by DD is less intuitive and can take a lot of effort, making the model hard to extend to new (vendor-specific) protocols or features. Therefore, we leverage *Differential Datalog (DDlog)* [2], a

Datalog programming language built on top of DD. In the following, we give some preliminary to Datalog, and introduce our DDlog-based control plane model.

A Datalog program consists of a set of *facts* and *rules*. A fact is a statement like "interface *intf* of router *X* has OSPF cost *cost*". This fact can be represented with `OSPFCost`$(X, intf, cost)$, where `OSPFCost` is termed a *relation*. A rule takes the form of $R_1(u_1) : -R_2(u_2), \ldots, R_n(u_n)$, where each R_i is a relation, meaning $R_1(u_1)$ holds if $R_2(u_2), \ldots, R_n(u_n)$ hold. Given some *base facts*, one can derive new facts by firing the Datalog rules.

DDlog-based control plane model. The right of Figure 3 shows the corresponding DDlog rule for the corresponding dataflow model on the left. As we can see, DDlog allows us to only focus on how routes (i.e., facts) are derived, without caring about the sequence to join, map, or filter routes. Additionally, unlike other Datalog languages [5, 21], DDlog offers several useful data structures, such as vectors, which make the modeling of route computation much easier.

Figure 4 shows the flow of data in our DDlog-based control plane model. If relations *A* and *B* appear on the left and right side of a rule, respectively, then there is an edge from *B* to *A* in the graph. If multiple relations appear on the right side of a rule to derive relation *A*, we merge their edges to *A*.

There are three types of relations: input relations, output relations, and intermediate relations. The input relations contain base facts including: (1) configurations for routing protocols, e.g., `BGPNet` contains the subnets imported to BGP; (2) network topology, e.g., `Link` contains L3 links; and (3) external routes, e.g., `ExtRoute` contains routes announced by ISPs that are out of scope of our model. There is a single output relation, i.e., `FIB`, and multiple intermediate relations, e.g., `GlobalRIB` which contain derived facts, e.g., routes.

The DDlog-based control plane model treats changes in the control plane as insertions and deletions of facts in input relations. For example, modifying the OSPF cost on interface 3 of router *D* from 10 to 100, is treated as two changes $-$`OSPFCost`$(D, 3, 10)$ and $+$`OSPFCost`$(D, 3, 100)$. The resultant changes in data plane state are insertions and deletions of facts in the output relation, i.e., `FIB`.

4.2 Executing the control plane model

The control plane model, which is a DDlog program, will be compiled into a DD program for execution. When executing the DD program, changes are propagated in the dataflow graph, and at each operator the changes in input will be mapped to changes in output. Since the dataflow is recursive, the propagation continues for multiple iterations, until there are no more changes (fixed point is reached). The insertions and deletions in the output relation `FIB` will be returned, and will be fed to Stage 2 (§5).

Figure 5 shows the execution of the control plane model for our example network. We have over-simplified the execution
(a) The dataflow graph

(b) The Datalog program

Figure 3: Part of dataflow graph with the corresponding Datalog program snippet for OSPF route propagation.

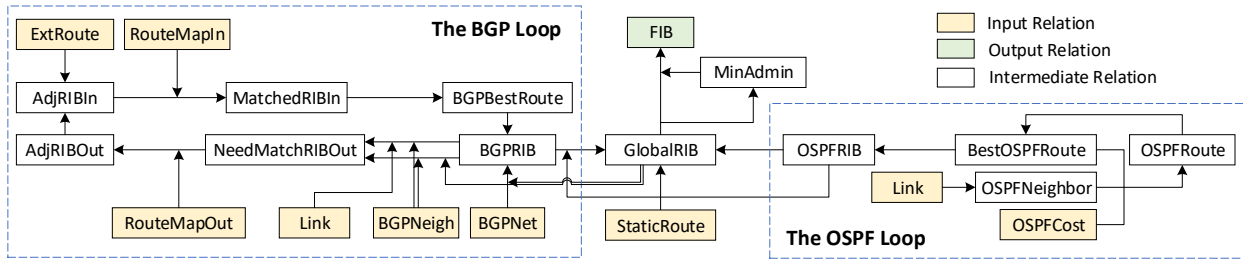

Figure 4: The flow of data in our control plane model. For simplicity, only the core relations are shown.

Figure 5: Control plane simulation for the example network.

by removing changes to a lot of intermediate relations and only focusing on changes to `Link`, `AdjRIBIn`, `BGPRIB`, and `FIB`. Here, the link failure $-(C,E)$ is input to the DD computation engine. The deletion will be `join`ed with existing facts in `BGPRIB` to derive new facts. Since the change is a deletion so the changes it derives are also deletions. After multiple intermediate steps, the change derives $-(C, 1.1.1/24, [E])$ and $-(C, 1.1.2/24, [E])$ in `AdjRIBIn`, meaning deletions of the received routes for prefixes 1.1.1.0/24 and 1.1.2.0/24 with AS path $[E]$ at router C. These two deletions in `AdjRIBIn` will trigger deletions of the old best routes and insertions of the new best routes for router C in `BGPRIB`. The changes in `BGPRIB` will then be joined with `GlobalRIB` to generate four changes in the output relation `FIB`. For simplicity, only the join of two deletions in `BGPRIB` and the corresponding fact in `GlobalRIB` are shown in Figure 5.

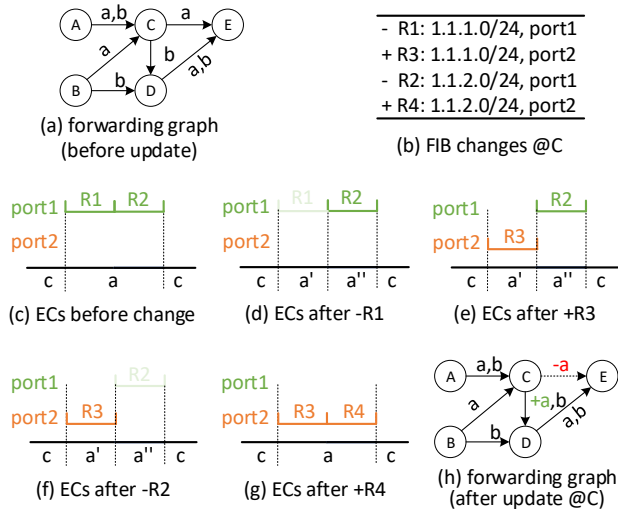
4.3 Optimizations

Customizing functions for efficiency. As noted above, using operators like `join` and `map` in DD can express simple operations like route propagation (routes are sent to neighboring routers, costs are updated, etc.). However, directly modeling more complex operations—e.g., BGP best route selection, applying route policies, etc.—using these DD operators requires a lot of operators, making the evaluation less efficient.

For example, suppose we select best routes from received routes R based on two conditions: local preference (LocPref) and path length (PathLen). Using DD, we need to group routes in R by prefix and use the aggregation function `max` to compute the highest LocPref value for each prefix, and then `join` the resultant collection $R1$ with R to obtain another collection $R2$ which contains routes with the highest LocPref. Similarly, we need to compute another two collections for PathLen. Correspondingly, if we use DDlog, we need to declare two rules and two relations for each condition. The original Datalog-based version of Batfish [14] used the above approach to realize BGP best route selection. Since there are many criteria for BGP best route selection (Cisco uses 13 criteria), we need a lot of DD operators, or correspondingly a lot of DDlog rules, making the model inefficient to evaluate.

To make the model efficient to evaluate, we realize complex operations (e.g., best route selection and route policies) with customized functions, which can be wrapped inside a `Reduce` operator offered by DD. Appendix C gives the code snippet of the function for best routes selection. In our experiments, by just customizing the process of best route selection, we can achieve a ~40% speedup (§8.1).

Partitioning routes for parallel simulation. For the same routing protocol, the propagation of different routes (prefixes) are largely independent. In the absence of route aggregations, two BGP routes 1.1.1.0/24 and 1.1.2.0/24 propagate independently through the network. Therefore, we partition the routes of the same routing protocol into groups, for parallel evaluation, and merge their results to obtain the RIBs for this protocol. In the following, we discuss why this works when there are multiple protocols and route aggregations.

(1) Route Dependency. When there are multiple routing protocols, routes may have dependencies. For example, BGP routes may depend on the OSPF routes for the loopback inter-


(a) forwarding graph (before update)	- R1: 1.1.1.0/24, port1 + R3: 1.1.1.0/24, port2 - R2: 1.1.2.0/24, port1 + R4: 1.1.2.0/24, port2 (b) FIB changes @C

Figure 6: Data plane model update for the example network.

faces of all iBGP peers in the same AS. We adopt a simple approach where we group BGP routes and OSPF routes separately, and schedule BGP groups only after all OSPF groups are finished. More sophisticated scheduling [37] can be used to handle more complex dependencies.

(2) Route Aggregation. Sometimes, different routes may be correlated due to `route aggregation`. For example, a router can aggregate routes for 1.1.1.0/24 and 1.1.2.0/24 into a single route (1.1.0.0/16) when advertising to its neighbors. Although it may seem this correlation prevents routes for 1.1.1.0/24 and 1.1.2.0/24 from being computed separately, our method is not affected since each instance has all the rules and base facts describing route aggregation. Thus, even if these two routes are in different groups, both of them can be aggregated into 1.1.0.0/16. We can remove the duplicated routes of 1.1.0.0/16 when merging the routes of multiple instances.

5 Differential Data Plane Modeling

As the second stage, DNA maps differences in data plane state to differences in the data plane model. We accomplish this using APKeep [48], a state-of-the-art data plane model.

In the following, we first show that updating the model by treating each data plane update separately can result in redundant computation, and then show how DNA can leverage correlation among rule updates to reduce such redundancy.

5.1 Single-rule model update

We return to the example network to show how APKeep updates the data plane model. We only consider the rule updates at Router C, as shown in Figure 6(b). The rule updates at Router B are quite similar and thus not discussed here.

Step 1. Identifying forwarding behavior changes. For each rule update, APKeep identifies the packets that change for-

warding behavior[1] by analyzing rule dependency. Returning to the example, after removing $R1$, APKeep determines that packets which previously match destination IP addresses in 1.1.1.0/24 will not match any lower-priority rule, and thus will be dropped. Then, the forwarding behavior change will be a 3-tuple $(1.1.1.0/24, port1, drop)$ which specifies the affected packets, old, and new output port, respectively.

Step 2. Updating the forwarding graph. For each change, APKeep updates the ECs, and transfers the updated ECs on the forwarding graph. Specifically, APKeep iterates over all ECs assigned to the old port, and check whether each EC belongs to or intersects with the affected packets. For the former, the EC will be transferred directly; while for the latter, the EC needs to be split before the transfer. In this example, the affected packets 1.1.1.0/24 will split EC a into two ECs, a' for 1.1.1.0/24, and a'' for 1.1.2.0/24, as shown in Figure 6(d). Then, a' will be transferred from port 1 to port $drop$ (a default port not shown here).

Figure 6(e) shows the insertion of $R3$, where step 1 identifies a behavior change $(1.1.1.0/24, drop, port2)$, and step 2 transfers a' from port $drop$ to port 2. Figure 6(f) shows the deletion of $R2$, and Figure 6(g) shows the insertion of $R4$, after which EC a' and EC a'' have the same forwarding behavior and are merged into a single EC a. Figure 6(h) shows the resulting differences of data plane model which are insertions/deletions of EC a on two edges.

In large networks, a configuration change may produce hundreds or thousands of rule updates, and performing the above two steps for each of them is slow. For example, failing a link in a fat tree with 180 routers results in over 3K rule updates. Even though a single rule update takes only 1ms, it still amounts to 3 seconds.

5.2 Batched model update

We observe that even when there are many rule updates, they are highly correlated, such that we can batch them to reduce redundant computation. In the following, we consider two types of correlations.

Correlation among rule insertions and deletions. Rule deletions are often accompanied by rule insertions for the same IP prefix. Many configuration changes like changing a BGP local preference or OSPF link cost will make the router change the best routes for some destination prefixes. Each change of best route would translate into a deletion of the old rule and an insertion of a new rule.

Based on the above correlation, we can *batch rule deletions and insertions* for step 1. Returning to our example, deleting $R1$ and inserting $R3$ requires updating the data plane model twice. However, by batching the deletion of $R1$ and insertion of $R3$, we can directly identify the change

---

[1] In this section "forwarding behavior" refers to hop-by-hop forwarding, not end-to-end forwarding.

as $(1.1.1.0/24, port1, port2)$. Therefore, we only need to run step 1 once. Moreover, step 1 will be more efficient since we do not need to analyze rule dependency. Similarly, by batching the deletion of $R2$ and insertion of $R4$, we can use another run of step 1 to identify a change $(1.1.2.0/24, port1, port2)$.

Correlation among rule updates on the same device. Rule updates on the same device are often quite similar, e.g., route deletions/insertions have the same output port. Many configuration changes like bringing down/up an interface will delete routes that output to the interface, and add new routes that output to other interfaces.

Based on the above correlation, we can *batch forwarding behavior changes on the same device* for step 2. Returning to the example, the two changes $(1.1.1.0/24, port1, port2)$ and $(1.1.2.0/24, port1, port2)$ have the same old port and the same new port. Instead of performing step 2 for each of these two changes, we can batch them as a single one $(1.1.1.0/24 \vee 1.1.2.0/24, port1, port2)$, and run step 2 only once. Moreover, we can directly transfer EC a from $port1$ to $port2$, without splitting a, further reducing computation overhead. Since step 2 needs to check all ECs of the old port, each involving a BDD operation, it dominates the overall running time of model update, and by batching changes for step 2, we can significantly reduce the overall running time.

In sum, APKeep needs to run the above two steps for each of the four rule updates, while after batching DNA only needs to run step 1 twice (without analyzing rule dependency), and step 2 once (without splitting and merging of ECs). As a result, DNA can directly update the model as Figure 6(g), avoiding intermediate steps shown in Figure 6(d)-(f).

Note that some of the batching methods can also be applied to other data plane verifiers. For example, Delta-net [18] can also be modified to leverage the first correlation. However, it is not clear how Delta-net can leverage the second correlation.

6 Differential Property Checking

This stage tracks network properties and returns differences, which we call *differential properties*. We focus on differential reachability, differential waypointing, and differential load balancing. In this section, we define these differential properties, and introduce an algorithm to efficiently compute them.

6.1 Defining differential properties

A network can be viewed as a big switch providing connectivity among entities including hosts, servers, middleboxes, external networks, etc. We term the ports at which these entities connect to the network as *edge ports*. We are interested in analyzing forwarding properties between the edge ports.

A forwarding property is defined in terms of a pair of edge ports (e_s, e_d), an equivalence class (ec), and other property-specific parameters. We focus on three types of properties:

| (a) old forwarding graph | (b) new forwarding graph |

Figure 7: Differential reachability computation for the example network.

- $Reach(e_s, e_d, ec)$—packets in ec can reach e_d from e_s.
- $Waypoint(e_s, e_d, ec, w)$—packets in ec can reach e_d from e_s, traversing waypoint w.
- $LoadBalance(e_s, e_d, ec, n)$—packets in ec can reach e_d from e_s and are load balanced among n forwarding paths.

Other properties like isolation, bounded path length, etc. [4, 6], can be similarly defined. $Properties_c$ denotes the set of properties control plane c satisfies.

Given two control planes c_1 and c_2, the differences in properties are defined as $\Delta Properties_{c_1 \to c_2} := Properties_{c_2} - Properties_{c_1}$. $\Delta Properties_{c_1 \to c_2}$ is a multiset, where each item can have multiplicity $+1$ or -1. In the following, we consider the change of configuration $c_1 \to c_2$, and omit the subscripts. For example, $\Delta Properties = \{-Reach(A_1, E_1, 1.2/16)\}$, then we know this prefix is previously reachable from A_1 to E_1, but becomes unreachable after the change. This is perhaps what the operators desire if they want to prevent A_1 from reaching the prefix at E_1, or it can be a violation of operator intent if it is unexpected. As another example, $\Delta Properties = \{-Waypoint(A_1, E_1, 1.2/16, C)\}$ means this prefix will no longer traverse the waypoint C, which may violate security policies. Finally, $\Delta Properties = \{-LoadBalance(B_1, E_1, 1.2/16, 2), +LoadBalance(B_1, E_1, 1.2/16, 1)\}$ means the number of (disjoint) paths between B_1 and E_1 decreases from 2 to 1, which may cause congestion. By looking at differences in properties, instead of compliance of (all or user-specified) properties, operators can better understand the impact of prospective changes to their networks.

6.2 Computing differential properties

In this section, we show how DNA incrementally computes differential properties. We use differential reachability as an example, and discuss how to extend to the other two properties. The left of Figure 7 shows the forwarding graph of the running example. There are three edge ports, and here we only show the reachability from port 1 of A and B (denoted as A_1 and B_1), to port 1 of E (denoted as E_1).

A straightforward way to compute differential reachability is to compute the reachability for the old forwarding graph (before change) and the new forwarding graph (after change), and compute the difference. The reachability for the old graph is computed as follows. First, we start from each edge port with all ECs. Then, at each node, we com-

pute the conjunction of these ECs with the ECs marked on the edges, and move to the next hop with the conjunction of ECs. The traversal stops until another edge port is reached. For example, starting from A_1, ECs a and b can reach E_1, therefore we have a reachability $Reach(A_1, E_1, \{a, b\})$; similarly, we also have $Reach(B_1, E_1, \{a, b\})$. The reachability for the new graph is computed in a similar way, resulting in $Reach(A_1, E_1, \{b\})$ and $Reach(B_1, E_1, \{a, b\})$. Therefore $\Delta Properties_{c_1 \rightarrow c_2} = \{-Reach(A_1, E_1, a)\}$. We name this straightforward method as TraverseAll.

According to our experiment, the TraverseAll method can take tens to thousands of seconds to compute the differential rechability. To reduce the running time, we apply the following two optimizations.

(1) Only traversing with ECs whose forwarding behaviors are affected. In this example, we only need to start the traversal with EC a, since EC b is not affected. This optimization has been used by exiting realtime data plane verifiers, which check loops or blackholes by only traversing with those affected ECs. We name this method as TraverseAll-Inc. However, even there are only few ECs affected, TraverseAll-Inc still needs to enumerate all the pairs of edge ports, which can still take a long time if the network is large.

(2) Directly traversing from change points instead of from all edge ports. Here change points refer to nodes whose forwarding behaviors change (B and C in the example). Since the traversals before the change points are not affected, it is not necessary to start the traversal from each edge port, e.g., in this example we can start the traversal from B and C with EC a. To make this optimization work, we need to incrementally maintain intermediate state recording the traversal before the change points, that is, for each node, which edge ports can reach this node. For example, on the old forwarding graph, node C should know that EC a can reach C from A_1 and B_1, such that when the traversal from C reaches E_1, we can know the reachability from A_1 and B_1 to E_1.

DNA enables both these optimizations, where optimization (2) is enabled as follows. For each *node* and *ec*, DNA maintains a set $EdgeSet(ec, node)$, which stores all edge ports from which ec can reach *node*. In this example the content of $EdgeSet(a, node)$ is marked aside *node* on the forwarding graphs. When traversing, we need to update $EdgeSet$ according to the rule that if an $n_1 \in EdgeSet(ec, n_2)$, and ec can reach n_3 from n_2, then we have $n_1 \in EdgeSet(ec, n_3)$. In this example, when traversing from C to E on the old forwarding graph, since $A_1, B_1 \in EdgeSet(a, C)$, we can derive $A_1, B_1 \in EdgeSet(a, E)$. Since we are traversing the old graph, A_1, B_1 should be deleted from $EdgeSet(a, E)$, as shown on the right of Figure 7. On the contrary, when traversing the new graph, the derived entries should be inserted into $EdgeSet$. Interested reader can refer to Appendix A for the algorithm to compute differential reachability.

Computing differential waypointing and load balancing. Unlike reachability, computing differential waypointing and

load balancing requires tracking the forwarding paths between edge ports. Therefore, instead of maintaining the edge ports from which ec can reach *node*, $EdgeSet$ should maintain the forwarding path taken by ec before reaching *node*. When traversing, we need to update $EdgeSet$ according to the rule that if $p_1 \in EdgeSet(ec, n_1)$, and ec can reach n_2 from n_1, then we have $p_1||n_1 \in EdgeSet(ec, n_2)$, where p_1 is a forwarding path, and $p_1||n_1$ appends n_1 to p_1. For the running example, (B_1, B, C, E) will be deleted from $EdgeSet(a, E_1)$, and (B_1, B, D, E) will be inserted into $Edge(a, E_1)$ after the change. Suppose C is a waypoint, then the change in $EdgeSet(a, E_1)$ indicates that packets belonging to EC a, sent from B_1 will no longer traverse the waypoint C.

Computing properties under link failures. We can leverage differential property to compute properties under link failures. For example, we can compute reachability properties that hold when any single link can fail. First, we compute a set R of all reachability properties when no links fail, Then, we fail each link one by one, and after each failure we compute differential reachability. For each deletion of reachability property, we remove it from the set R. After failing each single link, R contains all reachability properties that hold under any single link failure.

7 Implementation

We implement DNA in Java. First, we use Batfish [1] to parse the configuration files into vendor-neutral configuration objects, and write a parser to generate a set of insertions of base facts for the DDlog program.

For stage 1, we model the control plane with 800 LOC in DDlog. The model currently supports BGP, OSPF, static routes, routing policies, redistribution, reflector, communities, etc. The control plane model is compiled by the DDlog compiler into a DD program for execution. For stage 2, we extend APKeep [48] to optimize the model update algorithm for batched rule updates. For stage 3, we implement an algorithm to compute differential reachability (Appendix A).

Additionally, we implement a scheduler in Python to parallelize the data plane generation. The scheduler uses the DDlog's CLI, and maintains multiple instances of the DDlog program, each of which is responsible for a group of prefixes.

8 Experiments

We evaluate DNA with both real and synthetic updates. We are interested in the following questions: (1) can DNA speed up differential property checking (§8.1 and §8.2)? (2) is incrementally simulating the control plane always better when the changes are large, and can parallelization help DNA better scale to large changes (§8.3)? (3) can DNA also speed up property checking under link failures (§8.4)?

Table 1: Types of synthesized changes.

ID	Update	Explanation
1	InterfaceUp	Bring up an interface
2	InterfaceDown	Shut down an interface
3	NetworkAdd	Add a subnet to advertise to BGP
4	NetworkDel	Delete a subnet to advertise to BGP
5	NeighborAdd	Add a BGP neighbor
6	NeighborDel	Delete a BGP neighbor
7	LocalPref	Change the local preference
8	MultiPath	Allow to select up to k paths
9	Aggregation	Add an aggregation rule
10	StaticRoute	Add a static route
Figure 8: The time for DNA to compute differential reachability for synthetic changes on fat trees.

Setup. We run all the experiments on a server with two 12-core Intel Xeon CPUs @ 2.3GHz and 256G memory. Unless otherwise specified, a single core is used for these methods (except Batfish which is multi-threaded).

8.1 Synthetic changes

First, we evaluate the running time of DNA with synthetic changes. Specifically, we use different sizes of fat trees running BGP, where each node is assigned a distinct AS number and peers with all its adjacent nodes. We synthesize 10 different types of change, as shown in Table 1. Updates (1) and (2) can be used to simulate link failures and recovery, respectively. Updates (3) and (4) can be used to simulate changes in external routes. Update (7) adds a route map to change the local preference for routes received at one interface from 100 to 150 (more preferred).

Figure 8 reports the running time for DNA to compute differential reachability. For comparison, we also include the results for computing all-pair reachability using Batfish, Minesweeper, and Tiramisu. These tools can then compute differences of the all-pair reachability afterwards (the time to compute difference is not counted here). As we can see, DNA achieves a second-level running time for each control plane update, which is at least 3 orders of magnitude faster than existing tools—Minesweeper's [6] and Tiramisu's [4] main bottleneck is the number of links and end-host pairs, respectively. Here, init corresponds to the time for DNA to initialize, i.e., taking the original configuration snapshot as input,

and running the three stages in the same way as processing a configuration update.

Figure 9 shows a breakdown of running time for the three stages, on fat tree (#node=500, #links=4000). As shown in Figure 9(a), DNA's control plane simulation takes less than 1 second for all updates except Update 8, while Batfish, which is not incremental, always takes 24 seconds. We also compare against a version of DNA without customized functions for best route selection (§4) (DNA$^-$), and observe the simulation is ∼40% faster with our customized functions. Although the absolute savings for a large fat tree is only ∼100ms, the difference is substantial when we consider link failures: e.g., control plane simulations for all single link failures (not shown) take ∼6 minutes longer with DNA$^-$.

As shown in Figure 9(b), directly running APKeep can take as long as 0.2 seconds, while DNA can achieve running time mostly less than 0.01 seconds. In most types of changes, DNA is 10× faster than directly running APKeep.

As shown in Figure 9(c), the TraverseAll method (traversing from all edge ports with all ECs) can takes as long as 400 seconds to recompute the all reachability properties. For TraverseAll-Inc (Traverse from all edge ports with only affected ECs) method runs mostly around 1 seconds, but can take more than 10 seconds for update 7 and 8. The reason is that in these two updates, the affected ECs appear at all edge ports, and TraverseAll-Inc still needs to traverse from all edge ports. In contrast, DNA takes around 0.1 seconds, a speedup of 1-2 orders of magnitude compared to TraverseAll-Inc. For Updates 9 and 10, DNA and TraverseAll-Inc take roughly the same small amount of time. The reason is that there are a small number of affected ECs, but a large number of change points. For example, adding a static route only affects ECs overlapping with the route. However, since the route will be advertised by BGP, the ECs will change forwarding behavior at all nodes in the network. Therefore, both DNA and TraverseAll-Inc need to traverse from all edge ports.

We also experiment on fat trees running OSPF, and the trend is similar. The results can be found in Appendix §B.

8.2 Real changes

In addition to synthesized change, we also experiment with a real trace of configuration changes collected from the backbone network of a university campus. In total, the network consists of 28 routers and 50 physical links, running OSPF. The trace consists of 67 configuration snapshots spanning over three months. We compute the differences among consecutive snapshots to create 66 updates, which are fed to DNA for verification. The statistics on the network updates has already been shown in Figure 1.

Figure 10 shows the running time for the three stages of DNA. We compare the overall running time with Batfish, since Minesweeper times out (>1h per update). Also, we include the results for Baseline, which uses Batfish to generate
(a) Stage 1. Control Plane Simulation

(b) Stage 2. Data Plane Modeling

(c) Stage 3. Property Checking

Figure 9: The breakdown of running time for synthetic changes on fat tree (#nodes=500, #links=4000).

(a) Overall running time

(c) Data Plane Modeling

(d) Property Checking

Figure 10: The time to verify configuration changes of campus network.

the new data plane, APKeep to update the data plane model, and Traverse-All to compute differential reachability. We can see that DNA takes <1 second per update for 90% of all updates, while Batfish takes >500 seconds per update. Baseline is faster than Batfish by using realtime verifier (i.e., APKeep), but still takes tens of seconds per update on average.

Also note that for ~20% of updates, the running time of DNA is less than 10ms. The reason is that for these updates, some interfaces or ACL rules are added without taking effect, and the output of the first stage is empty. The second and third stage are not even invoked. However, it is hard and risky to manually determine whether a change in configuration files has effect on the network, and without DNA we still need to check them using tools like Batfish or Minesweeper.

For control plane simulation, we compare the results of DNA with those of Batfish. For more than 90% of changes, the generation time is less than 0.12 seconds. While Batfish takes more than 4 seconds for each single change. This shows that incrementally generating data plane state is much faster than from scratch in real networks. For model update, DNA takes less than 1 second for 90% of changes, $10\times$ faster than APKeep. For reachability verification, DNA takes strictly less than 0.1 second, while traversing from all edge points with all or affected ECs can take several seconds.

Compared to the synthesized changes on fat trees, where stage 1 dominates the overall running time, here stage 2 dominates the overall running time. The reason is that the largest fat tree (500 nodes, running BGP) has only 5K ECs, while the campus network has 45K ECs, due to the existence of ACLs.

8.3 Large changes and parallel simulation

In the previous two experiments, we mainly focus on small configuration changes. However, a network can occasionally experience large-scale changes [27], which may affect a large number of devices. We simulate large changes by shutting down a large number of interfaces in the campus network.

Figure 11 reports the time for DNA to incrementally simulate the control plane when failing a different number of links. For comparison, we also include the results of Batfish. As we can see, when failing a small number of links (say <10), incrementally simulating the control plane is much faster; while when the number increases to over 25 (single core), the incremental simulation becomes even slower than generation from scratch. This means that incremental simulation outperforms from-scratch simulation as long as the change sizes are smaller than some threshold (in our case, 50%). While since most of real changes are small (§2.1), incremental simulation would mostly be a better choice.

We also note that parallelizing the control plane simulation can increase such a threshold. Specifically, incremental simulation with 24 cores has larger improvement for larger changes. Even all links in the network were disconnected, the incremental simulation time is still comparable with from-scratch generation using Batfish.

We further study the effect of parallelizing control plane simulation on different size fat trees. For both BGP and OSPF, we randomly fail one node as well as all links connected to this node. Figure 12 reports the control plane simulation time for DNA with different number of cores. We can see the simulation speed increases with the number of cores. Due to the overhead of parallel simulation, the speed-up is not significant when the total time is already small (e.g., <1 second).

8.4 Enumerating link failures

One verification task is to check reachability under any single link failure. Using Batfish we need to enumerate each link failure and Minesweeper relies on SMT solvers to search for a counterexample where a link failure breaks reachability. DNA can leverage the similarity between the no link failure and single link failure to enumerate all link failures efficiently.

In this experiment, we evaluate the time to check reachability policies with any single link failure, i.e., whether two
Figure 11: The running time for control plane simulation on the campus network.

Figure 12: The running time for control plane simulation on fat trees, for one node failure with multiple cores.

Figure 13: The total time for checking reachability under any single link failure. (n_1, n_2) represents fat tree with n_1 nodes and n_2 links.

hosts or ports are always reachable if any link can fail. We use two sizes of fat trees with 20 and 80 nodes, and three ISP topologies from Config2Spec. For each topology, we fail a link each time, and let DNA compute differential reachability.

For comparison, we run Batfish, Minesweeper, and Tiramisu to check the reachability between each pair of hosts on the same networks. We also include Config2Spec for comparison, since it is shown to outperform both Batfish and Minesweeper when checking all-pair reachability under link failures. Since Config2Spec also checks other properties like load balancing, we modify it to let it only compute all-pair reachability for a fair comparison.

As shown in Figure 13, DNA is at least 10× faster than Batfish and Minesweeper, 3× faster than Config2Spec, on all topologies. DNA is also faster than Tiramisu by 10× on the 80-node fat tree. The speedup of DNA on the three ISP topologies is not as remarkable as on fat trees. The reason is that the links on the ISP topologies are not as redundant as on fat trees, and a single link failure has a larger impact on reachability. The above results imply that by leveraging the similarity among network snapshots with and without a failed link, DNA can check reachability policies under any single link failure faster than existing control plane verifiers.

9 Related Work

Control plane simulation/emulation. Control plane verifiers have employed several approaches for simulating the control plane including: a Datalog engine [14], an explicit state model checker [37], a generalized variant of Dijkstra's algorithm [34], abstract interpretation [7], and custom simulation engines [1, 38, 45]. However, all these approaches restart the simulation from scratch when the control plane changes, and do not reuse any of the state from prior simulations. The preliminary version of this paper [47] introduces incremental network configuration verification, but does not parallelize incremental control plane simulation, and has limited support for incremental data plane modeling and property checking. Control plane emulators [32] can accommodate control plane changes in an incremental manner, but they scale poorly due to their use of actual routing protocol implementations.

Symbolic control plane verifiers. Symbolic control plane verifiers characterize the space of data planes the control

plane may produce using graph algorithms [4, 15], SMT constraints [6, 43], or binary decision diagrams [13]. Even though some incremental graph algorithms exist [29] and SMT solvers offer some support for incremental solving [11], these capabilities are not sufficient to accommodate arbitrary control plane changes.

Data plane verifiers. Realtime data plane verifiers [18, 23, 26, 44, 48] can quickly analyze data plane changes (e.g., forwarding rule insertions), but cannot directly analyze configuration changes. DNA uses a realtime data plane verifier, APKeep [48], as one of its building blocks, and modifies AP-Keep to batch data plane changes for efficient processing, Other realtime data plane verifiers could also be modified to batch data plane changes and be used in DNA. NoD [33] uses Datalog, but NoD is not realtime.

Specification mining. Policy Units [8], Config2Spec [9], and Anime [25] infer a network's end-to-end behaviors from its configurations. We could compute differences in end-to-end behavior by applying such tools before and after a configuration change. However, due to the prevalence of small configuration changes (§2.1), such an approach unnecessarily duplicates computation in the same manner as applying a control plane verifier before and after changes (§1).

10 Conclusion

Differential Network Analysis (DNA) addresses a critical gap in control plane analysis: efficiently and effectively identifying differences in end-to-end forwarding behaviors arising from control plane changes. DNA uses a three-stage process that leverages advances in differential dataflow programming frameworks and data plane verifiers, along with domain-specific optimizations. Our evaluations using real and synthetic control plane changes show that DNA is able to compute differences in reachability in a few seconds—up to 3 orders of magnitude faster than state-of-the-art control plane verifiers. Thus, DNA provides a promising approach for operators to assess the impact of control plane changes.

A   An Algorithm for Computing Differential Reachability

Algorithm 1 summarizes how DNA traverses the new forwarding graph while avoiding redundant traversal. The traversal for the old forwarding graph is the same except Lines 6, 7, and 10. For ease of notation, we represent each edge port as a special node termed *edge node*. We traverse from each change point *loc* with all the affected ECs *pkts* (Lines 2-3). Suppose we are traversing from v to w, then we generate $pkts'$ by intersecting *pkts* with the ECs that can be forwarded to w according to the data plane model (Line 15), and record this information in R (Line 16). $(loc, w, pkts) \in R$ if *pkts* can reach w from the change point *loc*. If w is another change point, where the affected ECs are $pkts''$, the traversal continues to w with $pkts' \backslash pkts''$ (Line 17-18). In this sense, we *delegate* the traversal of common ECs $pkts' \cap pkts''$ to the traversal starting from w, therefore avoiding the redundant traversal of common ECs. If w is not a change point, the traversal continues to w with $pkts'$ (Line 19-20). The traversal ends when the set of ECs becomes empty (Line 12-13).

After all traversals finish, the algorithm iterates over all affected EC δ, and for each EC, extracts the forwarding paths of δ (Line 5). Then, for each link (loc, w) on the path, it updates $EdgeSet(\delta, w)$ according to topological order of w (Line 6-7). If w is an edge node, it updates the reachability matrix *Reach* (Line 8-10).

Algorithm 1: `DiffReach`(*Graph*, *Changes*)

KATRA: Realtime Verification for Multilayer Networks

Ryan Beckett
Microsoft

Aarti Gupta
Princeton University

Abstract

We present a new verification algorithm to efficiently and incrementally verify arbitrarily *layered* network data planes that are implemented using packet encapsulation. Inspired by work on model checking of pushdown systems for recursive programs, we develop a verification algorithm for networks with packets consisting of *stacks* of headers. Our algorithm is based on a new technique that lazily "repairs" a decomposed stack of header sets on demand to account for cross-layer dependencies. We demonstrate how to integrate our approach with existing fast incremental data plane verifiers and have implemented our ideas in a tool called KATRA. Evaluating KATRA against an alternative approach based on equipping existing incremental verifiers to emulate finite header stacks, we show that KATRA is between 5x-32x faster for packets with just 2 headers (layers), and that its performance advantage grows with both network size and layering.

1 Introduction

The success of networks is in part due to their *layered* design where different protocol layers are delegated different responsibilities. For instance, many networks, including virtual networks [3, 16, 31], are designed in an overlay/underlay pattern that is implemented by encapsulating packets, e.g. using IP-in-IP [34], IP GRE [18], or VXLAN [30] tunnels. In a wide-area network (WAN), routing protocols such as iBGP and SDN solutions such as SWAN [19] rely on an underlying label-switching protocol like MPLS. In routers, Ethernet frames are encapsulated in IP headers to implement forwarding, and new and emerging technologies such as SD-WAN can connect two WANs together by tunneling packets to each other securely using IPSEC [28].

However, while this layered design has proven successful, allowing each layer to hide many details from others, it also makes operating networks reliably a challenge as many bugs can sit in the intersection of one or more of these layers [37]. Given the pervasiveness of layering as a fundamental design pattern in networks, it is critical that we be able to ensure the reliability of networks using this design. In practice, the implementation of layering is often extraordinarily complex. For instance, packets going over AT&T's backbone network consist of as many as eleven encapsulated headers [44].

To ensure the safe operation of multilayer networks, a natural technology to employ is that of network verification, which has emerged as a viable technique to proactively catch bugs and misconfigurations related to automation and human error. Employed by nearly all major cloud providers now [5, 17, 21, 39, 45], network verification has witnessed substantial practical use in industry as researchers have iteratively improved upon the scalability, responsiveness, and expressiveness of the underlying verification tools and techniques. Many of these tools are engineering marvels – through complex data structures and algorithms, they enable efficient verification of new network changes in milliseconds.

While recent progress in network verification has been substantial, existing tools typically analyze a single layer or component of the network stack. For example, most verification tools in use today analyze only the simple IP-based forwarding tables and ACLs [4, 7, 20, 21, 26, 27, 29, 41, 42, 46] governed by the control plane. To verify a network with N layers using verification tools today, one possibility is to model packets in the network as consisting of N duplicate copies of different headers (e.g., an IPv4 header). While this approach is possible, and researchers have proposed this approach in some prior work [42, 46], it suffers from two major problems.

The first problem is that the number of layers N may not be known a priori by the user of the verification tool. For instance, a network making use of the MPLS fast reroute (FRR) [14, 25, 33] protects links against failure by rerouting traffic that would have gone over the failed link along a predetermined backup tunnel. FRR schemes may encapsulate a packet's header a number of times that depends on the number of failures encountered by the packet along its path. Moreover, if a user provides an incorrect (low) estimate of N, then the verifier may report both false positives and false negatives.

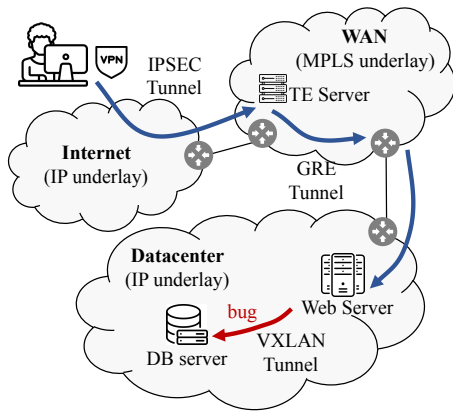
The second problem is that, even when the user is able to statically determine N, modeling this many packet headers simultaneously leads to a highly inefficient representation. Most network verifiers work by modeling the sets of packets that are reachable from each ingress and egress point in the network [27, 41, 42, 46], and such sets may grow substantially larger and more complex to process when capturing the dependencies between different headers in the packet. In our experiments (§7), even with just two layers, this simple approach can be anywhere from 5x-32x slower than necessary.


Figure 1: A user attempts to access a corporate web service.

Networking example	Layering mechanism
campus network isolation [44]	VLAN, VXLAN [30]
virtual private network [15]	IP-IP [34], IP GRE [18]
3G/4G mobile packet core [38]	GPRS tunneling [1]
interior gateway protocol [32]	LSPs, MPLS [35]
performance proxy [8]	IPSEC [28]
traffic engineering [43]	IP GRE [18]
software-defined WAN [13]	IPSEC [28]

Table 1: Example network services features with layering.

To address these problems, in this paper, we present KA-TRA, the first tool for real-time verification of layered networks – those networks that manipulate *stacks* of headers through packet encapsulation. Inspired by recent work on analyzing MPLS [22, 23], we leverage ideas from the verification of pushdown systems [36] used to model recursive programs. A key new idea is to keep a decomposed representation of the set of header stacks as a stack of header sets where the set of headers at one layer in the stack are treated as independent of those in another. When an operation modifies and later restricts packets at a given layer, it may be necessary to go back and "repair" the sets of packets representative of previous headers in the stack to account for this change.

We demonstrate how we can integrate our ideas with existing incremental data plane verifiers, and we implement KATRA as an extension to the state-of-the-art verifier AP-Keep [46]. In addition to being able to reason about arbitrarily large header stacks, for networks consisting of just two layers, we further demonstrate that KATRA can verify properties 5x-32x faster than an approach based on extending existing algorithms with a finite header stack encoding.

Our contributions with KATRA are the following:

- We present a new formal model, and its semantics, for layered networks that supports arbitrarily nested packet encapsulations and decapsulations.

- We develop an efficient algorithm for verifying layered networks in our model. The algorithm is based on a new notion of *partial* equivalence class as well as a new decomposed representation for symbolic header stacks.

- We implement our ideas in a tool called KATRA, which integrates our new model and algorithm with the state-of-the-art incremental verification approach based on APKeep [46].

- We evaluate KATRA against a baseline based on a finite header stack representation and demonstrate that KATRA is 5x-32x faster with this speedup growing larger with both network size and the number of network layers.

2 Motivation and Background

Protocol *layering* in networks is used pervasively as a way to separate concerns and build new features and services atop existing infrastructure. Consider the scenario depicted in Figure 1. In the example, an employee of a company attempts to access a corporate web service, that is hosted in the cloud, from their home. The employee uses a secure VPN connection so their traffic is encapsulated in an IPSEC [28] tunnel before being forwarded over the Internet. When the traffic traverses the cloud provider's wide area network (WAN), a traffic engineering server selects an egress point for a nearby data center. The WAN forwards packets to this egress using an IP-GRE tunnel over its MPLS-based core. Once the traffic reaches the data center, it is forwarded to the requested web server. The web server must now access data from a database (DB) server configured in the same virtual overlay network. The web server thus sends traffic to the DB server using a VXLAN tunnel configured atop an IP-based datacenter fabric.

In the example, layer 2 and layer 3 forwarding elements are combined to implement several abstractions. While this approach to protocol layering is powerful, if any one of the forwarding policies at any layer in the example is misconfigured, then the user will not be able to reach the intended service. For instance, if there were a misconfigured security rule in the overlay network between the web and DB servers then the user may lose connectivity to the web service. Similarly, a misconfiguration in the datacenter's IP-based underlay network could break connectivity. To make matters worse, when network forwarding bugs span multiple layers, identifying the root cause of the issue can be complicated as it may require coordination between multiple different teams spread across one or more organizations [37], each with only a partial view of the network as a whole.

Multilayer verification. Network verification is a natural fit to ensure the correctness of multilayer networks, yet verifiers today were not built with layering in mind. Existing verifiers assume that packets have a fixed size header rather than an expandable *stack* of headers. While it is sometimes possible to retroactively analyze such multilayer networks using existing verifiers by pessimistically modeling a "worst case" fixed size header stack, doing so is often highly inefficient.

3   Layered Network Model

Rather than model networks with fixed size headers, as is done by existing network verifiers, in this section we define a new network model that includes protocol layering as a first class concern. We model multilayer networks as operating on an unbounded *stack* of headers. We then demonstrate that one can view both single-layer and multi-layer networks as instances of our general model.

3.1   Notation and Preliminaries

Before defining our network model, we first introduce some notation and preliminary definitions.

Definition 3.1 (Sequences). *For a set X, we use the notation X^* to mean the set of all possible sequences of elements of X. We define a sequence $\sigma \in X^*$ inductively as either ε representing the empty sequence, or the concatenation $(\sigma' \cdot x)$ of another sequence $\sigma' \in X^*$ together with an element $x \in X$.*

For simplicity of notation, we sometimes write a sequence $\sigma \in X^*$ as $\sigma = x_0 \cdot x_1 \cdot \cdots \cdot x_n$ where $x_i \in X$ and x_0 is the first element of the sequence and x_n is the last element, and we omit writing out the ε. Concatenation of two sequences is defined recursively as $\sigma \cdot \varepsilon = \sigma$ and $\sigma \cdot (\sigma' \cdot x) = (\sigma \cdot \sigma') \cdot x$ As a shorthand, for a sequence $\sigma = \sigma' \cdot x$ we define $\text{top}(\sigma) = x$ and $\text{bot}(\sigma) = \sigma'$. These two partial functions are undefined when $\sigma = \varepsilon$. Finally, we write $|\sigma|$ to mean the length of a sequence such that $|\varepsilon| = 0$ and $|\sigma \cdot x| = 1 + |\sigma|$. A stack is a sequence σ where the top of the stack is given by $\text{top}(\sigma)$.

For sets X and Y, we use the standard notation Y^X or $X \to Y$ to mean the set of functions from X to Y. Similarly, we use the notation $X \hookrightarrow Y$ to represent partial functions from X to Y. Given a (potentially partial) function f from X to Y and function g from Y to Z, we write $f \circ g$ to define their composition, from X to Z.

3.2   Formal network model

We define a network $\mathcal{N}$ as a tuple $\langle V, E, \mathcal{H}, \mathcal{T}, \mathcal{R} \rangle$ where:

- V is a set of vertices, and $E \subseteq 2^{V \times V}$ is a set of edges. Edges are unidirectional and we represent bidirectional edges with a pair of edges. For edge $e = \langle u, v \rangle$, we use the notation $\text{src}(e) = u$ and $\text{tgt}(e) = v$.

- $\mathcal{H}$ is a set of valid headers for the protocols in use.

- $\mathcal{T}$ is a set of transformations, which are partial functions over packet headers of type $\mathcal{T} \subseteq 2^{\mathcal{H} \hookrightarrow \mathcal{H}}$.

- $\mathcal{R}$ is a set of rules $\mathcal{R} \subseteq \mathbb{N} \times E \times 2^{\mathcal{H}} \times \mathcal{T}$. For rule $r \in \mathcal{R}$ where $r = \langle p, e, m, \tau \rangle$. We use the notation $\text{priority}(r) = p, \text{edge}(r) = e, \text{match}(r) = m$, and $\text{modify}(r) = \tau$ to refer to the components of the rule.

Intuitively, lower priority rules take precedence over those with higher priority at a given node. The best rule for a given header at a node is the rule with lowest priority at that node that also matches the header.

Definition 3.2 (Best rule). *For a node $u \in V$ and a header $h \in \mathcal{H}$, we define the best matching rule at u as:* $\Omega(u,h) = \min_{\text{priority}}\{r \in \mathcal{R} \mid \text{src}(\text{edge}(r)) = u, \ h \in \text{match}(r)\}$

For simplicity, we assume that there is always a unique best rule for a given header. This is ensured by requiring that (1) rule priorities must be unique, and (2) all headers are matched by at least one rule. In practice, one can ensure this requirement is met by adding a maximum priority default rule that matches all other unmatched headers.

3.3   Network semantics

Given a header $h \in \mathcal{H}$ and an initial node $u \in V$, which we call a located packet $L = V \times \mathcal{H}$, the network produces a sequence of new located packets to capture the packet's history as it goes through the network. Specifically, we define the semantics of a network $\mathcal{N}$ as a function $[\![\mathcal{N}]\!]_i : L \to L^*$ that takes an initial located packet to a trace of located packets through the network for a given number of steps $i \in \mathbb{N}$:

$$[\![\mathcal{N}]\!]_i\langle u, h \rangle = \begin{cases} \varepsilon \cdot \langle u, h \rangle & \text{if } i = 0 \\ \sigma & \text{elif } \tau(h') \text{ undefined} \\ \sigma \cdot \langle v, \tau(h') \rangle & \text{otherwise} \end{cases}$$

where $\sigma = [\![\mathcal{N}]\!]_{i-1}\langle u, h \rangle$ and $\text{top}(\sigma) = \langle u', h' \rangle$ and:

$$\begin{aligned} \tau &= \text{modify}(\Omega(u', h')) \\ v &= \text{tgt}(\text{edge}(\Omega(u', h'))) \end{aligned}$$

Definition 3.3 (Packet termination). *We say network $\mathcal{N}$ has terminated a located packet ℓ after i steps, written $\mathcal{N} \otimes \langle i, \ell \rangle$, if the trace no longer changes:* $[\![\mathcal{N}]\!]_i \ell = [\![\mathcal{N}]\!]_{i-1} \ell$.

3.4   Lifting networks to layered networks

To implement layering, conceptually packets contain an unbounded stack of headers to which the network can push or pop. A layered network is just an instance of a network that processes *stacks* of headers:

Definition 3.4 (Multilayer network). *A multilayer network is an instance of a network $\mathcal{N} = \langle V, E, \mathcal{H}^*, \mathcal{T}, \mathcal{R} \rangle$ over sequences of headers $\mathcal{H}^*$ with some restrictions on $\mathcal{T}$ and $\mathcal{R}$.*

Primarily, we require that every transformation $\tau \in \mathcal{T}$ and every rule match set $\text{match}(r)$ for $r \in \mathcal{R}$ only inspects or modifies the top of the stack[1]. In other words, we often write that $\tau(\sigma \cdot x) = \sigma \cdot \tau(x)$. And that $\sigma \cdot h \in \text{match}(r) \iff h \in \text{match}(r)$ as though τ and $\text{match}(r)$ were defined over $\mathcal{H}$. The

---

[1]This restriction can express encapsulation and decapsulation in real networks yet also makes verification tractable.
rule	p	e	m	τ
r_0	100	$\langle c_1, v_1 \rangle$	$\mathcal{H}^*$	τ_{id}
r_1	100	$\langle v_1, v_1 \rangle$	$\phi_{\text{dst}}(23.1.4.0/24)$	$\tau_{\text{push}} \circ \tau_{\text{tunl}}$
r_2	200	$\langle v_1, v_2 \rangle$	$\phi_{\text{dst}}(10.0.1.0/24)$	τ_{id}
r_3	300	$\langle v_1, v_1 \rangle$	$\mathcal{H}^*$	τ_{drop}
r_4	100	$\langle v_2, v_3 \rangle$	$\phi_{\text{dst}}(10.0.1.0/24)$	τ_{id}
r_5	200	$\langle v_2, v_2 \rangle$	$\mathcal{H}^*$	τ_{drop}
r_6	100	$\langle v_3, v_3 \rangle$	$\phi_{\text{src}}(t_s) \cap \phi_{\text{dst}}(t_d)$	τ_{pop}
r_7	200	$\langle v_3, c_2 \rangle$	$\mathcal{H}^*$	τ_{id}
r_8	100	$\langle c_2, c_2 \rangle$	$\mathcal{H}^*$	τ_{delv}

Figure 2: Example formulation of a network with a single tunnel between v_1 and v_3. We use the notation $\phi_f(P)$ for set P as a shorthand to mean packets where the field f is contained in P. Thus $\phi_{\text{dst}}(P) = \{\sigma \in \mathcal{H}^* \mid \langle d, s \rangle \in \text{top}(\sigma), d \in P\}$. Tunneled packets are encapsulated by first executing τ_{push} to duplicate the top-most header before modifying this header copy with τ_{tunl} to set to source ip to $t_s = 10.0.2.0$ and the destination ip to $t_d = 10.0.1.0$. Packets are then forwarded according to the underlay network towards $t_d \in 10.0.1.0/24$ hosted at v_3. Packets at v_3 are decapsulated by popping the top-most header and then delivered to client c_2.

only exception to this restriction is for two special transformations τ_{push}, which makes a new copy of the current top of the stack, and τ_{pop}, which drops or decapsulates the top of the stack. More specifically, we define $\tau_{\text{push}}(\sigma \cdot x) = \sigma \cdot x \cdot x$ and we define $\tau_{\text{pop}}(\sigma \cdot x \cdot y) = \sigma \cdot x$. Both transformations are undefined otherwise and may be composed with other transformations (e.g., $\tau \circ \tau_{\text{push}}$).

Example Network. To make the model more concrete, we show an example of its instantiation in Figure 2. The network in the figure is given by the tuple $\mathcal{N} = \langle V, E, \mathcal{H}^*, \mathcal{T}, \mathcal{R} \rangle$ where the nodes and edges are defined by the sets:

$$V = \{c_1, v_1, v_2, v_3, c_2\}$$
$$E = \{\langle c_1, v_1 \rangle, \langle v_1, v_1 \rangle, \langle v_1, v_2 \rangle, \langle v_2, v_3 \rangle, \langle v_3, v_3 \rangle, \langle v_3, c_2 \rangle\}$$

Note that the edges include self edges (e.g., $\langle v_1, v_1 \rangle$) to model recursive lookup for forwarding and tunneling.

The set of headers $\mathcal{H} = \{\langle d, s \rangle \mid d, s \in \{0, \dots, 2^{32} - 1\}\}$ defines headers consisting of two 32-bit IP address fields for destination and source IP, and $\mathcal{H}^*$ is all sequences (stacks) of such headers. The set of transformations for the network is given by $\mathcal{T} = \{\tau_{\text{id}}, \tau_{\text{drop}}, \tau_{\text{delv}}, \tau_{\text{push}} \circ \tau_{\text{tunl}}, \tau_{\text{pop}}\}$. The transformation τ_{id} is the identity transformation such that $\tau_{\text{id}}(\sigma) = \sigma$, τ_{drop} and τ_{delv} are transformations that are undefined for all inputs and thus terminate traffic, τ_{tunl} is a transformation that

i	$\text{top}(\llbracket \mathcal{N} \rrbracket_i \langle c_1, \langle d, s \rangle \rangle)$	description
0	$\langle c_1, \langle d, s \rangle \rangle$	*forward to v_1*

5	$\langle v_3, \langle d, s \rangle \rangle$	*forward to c_2*
≥ 6	$\langle c_2, \langle d, s \rangle \rangle$	*delivered*

Table 2: Trace of a packet with source s and destination d from client node c_1 in the network shown in Figure 2.

rewrites the source IP address to t_s and the destination IP address to t_d. The composed transformation $\tau_{\text{push}} \circ \tau_{\text{tunl}}$ first creates a copy of the top of the stack and then rewrites the IP addresses according to τ_{tunl} for the encapsulated header.

A trace through the network given by the semantics (see §3.3) represents the packet forwarding in the network. Consider sending an initial packet from client c_1 with some destination address $d \in \phi_{\text{dst}}(23.1.4.0/24)$ and some arbitrary source address s. The top of the trace given by the semantics $\llbracket \mathcal{N} \rrbracket_i \langle c_1, \langle d, s \rangle \rangle$ is shown in Table 2.

4 Realtime Verification of Layered Networks

Given a network $\mathcal{N} = \langle V, E, \mathcal{H}^*, \mathcal{T}, \mathcal{R} \rangle$ over stacks of headers $\mathcal{H}^*$ and a new rule r being inserted or removed from $\mathcal{R}$, our goal is to incrementally verify the correctness of $\mathcal{N}$ with respect to some user defined properties of interest.

In this section we first give a brief overview of how existing incremental verification algorithms work for finite header sets $\mathcal{H}$ (§4.1). We then show how this notion of equivalence class falls apart for the infinite space of header stacks $\mathcal{H}^*$, which leads existing algorithms to not terminate. To solve this problem, we define a new notion of *partial* equivalence class based on only the top of the header stack (§4.2). Partial equivalence classes can be computed efficiently, however they do not necessarily guarantee equivalent network-wide behavior. Instead, we develop an algorithm that lazily refines these classes while verifying properties (§4.3 and §4.4).

4.1 Existing incremental verifiers

Most incremental data plane verifiers today work by analyzing the network rules $\mathcal{R}$ and, based on that analysis, dividing the headers $\mathcal{H}$ into subsets that have the same forwarding behavior, which can then be checked using graph algorithms. More specifically equivalence classes are defined as:

Definition 4.1 (Trace hops). *Given a trace σ (from §3.3) consisting of located packets L, we define function $\text{hops}(\sigma)$, which produces only the nodes in the trace, inductively over σ as $\text{hops}(\varepsilon) = \varepsilon$ and $\text{hops}(\sigma' \cdot \langle u, h \rangle) = \text{hops}(\sigma') \cdot u$.*

Definition 4.2 (Equivalence classes). *A set of header sets* $\{\mathcal{H}_1,\ldots,\mathcal{H}_n\}$ *are equivalence classes for a network* $\mathcal{N} = \langle V, E, \mathcal{H}, \mathcal{T}, \mathcal{R} \rangle$ *if the following conditions hold:*

- $\mathcal{H} = \mathcal{H}_1 \cup \ldots \cup \mathcal{H}_n$ *(complete)*
- $\forall i, j \in \{1,..,n\}, i \neq j \Rightarrow \mathcal{H}_i \cap \mathcal{H}_j = \emptyset$ *(disjoint)*
- $\forall j \in \{1,..,n\}, \forall h_1, h_2 \in \mathcal{H}_j, \forall u \in V, \forall i \in \mathbb{N},$ *(g-equiv)*
  $\mathrm{hops}(\llbracket \mathcal{N} \rrbracket_i \langle u, h_1 \rangle) = \mathrm{hops}(\llbracket \mathcal{N} \rrbracket_i \langle u, h_2 \rangle)$

Existing incremental verification tools compute an over-approximate set of equivalence classes $\{\mathcal{H}_1,\ldots,\mathcal{H}_n\}$ using intricate data structures such as multi-dimentional tries [29] and Binary Decision Diagrams (BDDs) [46]. While early work on incremental verification such as Veriflow [29] and Deltanet [20] could not handle rule transformations (i.e., all transformations must be τ_{id}), more recent work such as AP [42] and APKeep [46] can account for transformations.

At a high-level, these tools work as follows. First, they compute a set of equivalence classes $\{\mathcal{H}_1,\ldots,\mathcal{H}_n\}$ based on the rule match fields. Next, for each transformation $\tau \in \mathcal{T}$ and each $i \in \{1,..,n\}$, they compute $\tau(\mathcal{H}_i) = \{\tau(h) \mid h \in \mathcal{H}_i\}$. Since the transformed sets may now violate the disjoint condition, the resulting set $\{\mathcal{H}_1,\ldots,\mathcal{H}_n, \tau(\mathcal{H}_1),\ldots,\tau(\mathcal{H}_n)\}$ is made disjoint by dividing up these sets. This process is iterated with all transformations until no more changes occur.

The problem with equivalence classes. There are several problems that occur when trying to lift this approach to equivalence class generation to *stacks* of headers. One problem is that the space of header stacks $\mathcal{H}^*$ is infinite and symbolic data structures in existing tools cannot represent and manipulate infinite sets of values. This is generally a hard problem, which we solve in §4.3.

Even with data structures to manipulate such infinite sets, the algorithm discussed previously does not necessarily terminate in this infinite space. For instance, an equivalence class for stacks with a single header: $\mathcal{H}_i^* = \{\varepsilon \cdot h \mid h \in \mathcal{H}\}$ does not terminate with τ_{push} – one would compute a new equivalence class for packets with two headers, then three, and so on.

4.2 Partial equivalence classes

To solve this problem, we introduce a new notion of *partial* equivalence classes. Partial equivalence classes capture sets of packets that will have the same forwarding behavior at every node in the network but may not be transformed unambiguously by transformations to other partial equivalence classes. Formally, we define them as:

Definition 4.3 (Partial Equivalence Classes). *A set of header sets* $\{\mathcal{H}_1,\ldots,\mathcal{H}_n\}$ *are partial equivalences classes for a network* $\mathcal{N} = \langle V, E, \mathcal{H}, \mathcal{T}, \mathcal{R} \rangle$ *if the following hold:*

- $\mathcal{H} = \mathcal{H}_1 \cup \ldots \cup \mathcal{H}_n$ *(complete)*
- $\forall i, j \in \{1,..,n\}, i \neq j \Rightarrow \mathcal{H}_i \cap \mathcal{H}_j = \emptyset$ *(disjoint)*
- $\forall j \in \{1,..,n\}, \forall h_1, h_2 \in \mathcal{H}_j, \forall u \in V,$ *(l-equiv)*
  $\mathrm{edge}(\Omega(u, h_1)) = \mathrm{edge}(\Omega(u, h_2)) \wedge$
  $\mathrm{modify}(\Omega(u, h_1)) = \mathrm{modify}(\Omega(u, h_2))$

The difference between partial equivalence classes and equivalence classes (Definition 4.2) is subtle. We demonstrate the difference in Figure 3. In the example, packet headers consist of a destination IP field and time-to-live (TTL) field. If we ignore the layering transformations τ_{push} and τ_{pop}, which make the example not terminate, existing tools AP and AP-Keep would compute the equivalence classes shown in Figure 3b according to Definition 4.2. There are 257 equivalence classes. This large number comes from repeatedly applying τ_{ttl} to compute the transitive closure of equivalence classes as described in §4.1. In contrast, there are only 3 partial equivalence classes for the example, shown in Figure 3c since they depend only on local forwarding behavior.

Note that partial equivalence classes do not guarantee equivalent end-to-end behavior of packets, only local forwarding. For instance the packets $\langle 10.7.1.2, 255 \rangle$ and $\langle 10.7.1.2, 1 \rangle$ belong to the same partial equivalence class (2) in Figure 3c. Yet when sent from v_1, the latter packet will be dropped at v_2 while the former will be forwarded to v_3.

Of importance is that the definition of partial equivalence classes depends only on the rule transformations τ applied rather than the application of $\tau(\mathcal{H}_i)$ to some set of packets. This means that we can compute partial equivalence classes efficiently for header stacks using techniques similar to that of prior work [46] by looking only at the top of the stack.
4.3 Verification algorithm overview

Given a set of (changed) partial equivalence classes and a property P, our objective is to check whether P holds for all packets in all of the (changed) partial equivalence classes.

Our approach is as follows: given a set of partial equivalence classes $\{\mathcal{H}_1,\ldots,\mathcal{H}_n\}$ we start by exploring the reachable paths from every source node using a depth-first search. At each node u, packets in the partial equivalence class for $\mathcal{H}_i$ will all have the same next hop v and transformation τ (by definition). We proceed to apply $\tau(\mathcal{H}_i)$ to get some new set of packets $\mathcal{H}_i'$. Because $\mathcal{H}_i'$ may partially overlap with one or more existing partial equivalence classes, we identify all other partial equivalence classes $\mathcal{H}_{i_1},\ldots,\mathcal{H}_{i_m}$ such that $\forall j \in \{1,..,m\}, \mathcal{H}_i' \cap \mathcal{H}_{i_j} \neq \emptyset$. We then continue the search with each subset $(\mathcal{H}_i' \cap \mathcal{H}_{i_j})$.

Representing header stacks. We still have the problem of symbolically representing the infinite space of stacks of headers $\mathcal{H}^*$. To do so, we use a decomposed representation where we model a set of header stacks as a concrete stack of symbolic header sets. For instance, suppose the set of reachable header stacks at a given node is $\{\varepsilon \cdot h_1 \cdot h_2, \ \varepsilon \cdot h_3 \cdot h_4\}$. We instead represent this set as the stack of header sets given by the stack $\varepsilon \cdot \{h_1, h_3\} \cdot \{h_2, h_4\}$.

Of course, this decomposed representation naturally over approximates the set of headers (e.g., it would appear that $\varepsilon \cdot h_1 \cdot h_4$ is a reachable header stack). However, by carefully tracking the transformations that modify the stack (e.g., that

Figure 3: Running example of computing reachability in a simple multilayer network. Example network has headers consisting of a destination IP and a time-to-live (TTL) field: $h \in \mathcal{H} = \langle d, t \rangle$ where $d \in \{0, .., 2^{32} - 1\}$ and $t \in \{0, .., 255\}$. The transformation τ_{ttl} decrements the TTL field. (a) shows APKeep equivalence classes for the single-layer version of the network and (b) Katra's partial equivalence classes for the multi-layer version.

only h_1 leads to h_2 and only h_3 leads to h_4), this representation remains precise. On the other hand, the decomposed representation is convenient because it allows for modeling arbitrary sized stacks and can execute τ_{push} and τ_{pop} cheaply on the symbolic representation since it is just a concrete stack operation. It also lets us leverage existing efficient data structures such as those based on BDDs, to manipulate the stacks despite not having a fixed size.

Given a decomposed stack of header sets $\sigma = \varepsilon \cdot H_1 \cdot \ldots \cdot H_n$ the usual definitions for τ_{push} and τ_{pop} apply, and we use a definition of a transformation τ applied to stacks: $\tau(\sigma \cdot h) = \sigma \cdot \tau(H)$. One drawback with this definition is that the headers at different layers of the stack lose dependencies between them. For instance, if the stack $\varepsilon \cdot H_1 \cdot H_1$ is filtered and becomes $\varepsilon \cdot H_1 \cdot H_2$, it may be that the new stack should be $\varepsilon \cdot H_2 \cdot H_2$ since only those packets with the inner header in H_2 would have pushed to headers that later survived the filter. In general, we track the transformations applied to the headers at each layer of the stack, and then "repair" the stack on demand whenever our representation is at risk of losing precision.

4.4 Layered verification algorithm

The algorithm for verifying arbitrarily layered networks is shown in Algorithm 1. CheckProperty takes as input the network $\mathcal{N}$, the partial equivalence class (e.g., one that changed after a rule insertion or deletion) $\mathcal{H}_i$, a set of source nodes S, a destination node d, and a path property P to check for each pair of source and destination.

The algorithm starts by running a depth-first search from each source node $s \in S$ (line 7) and tracking the visited nodes. Each node in the algorithm contains (i) a topology node, (ii) the current partial equivalence class (initially $\mathcal{H}_i$), and (iii) the current symbolic stack (initially $\varepsilon \cdot \mathcal{H}_i$). An invariant of the

algorithm is that the top of the symbolic stack is a subset of the current partial equivalence class.

The depth-first search first looks up the next hop (edge and transformation τ on line 11) for the current partial equivalence class $\mathcal{H}_i$ and node u. It then applies the transformation τ to the current stack (line 12). If τ is undefined for this stack, then the trace is terminated and the algorithm checks the property P on the path (stored in the previous pointers starting at u on line 14). If the property fails, it returns a counter example.

Otherwise, the algorithm inspects the new top of the stack σ and finds all new overlapping partial equivalence classes $\mathcal{H}_{i_j}$ (line 16). For each, it computes a new stack σ' (line 17) obtained by restricting the top of the stack to this new partial equivalence class. If the top of the stack changed it then "repairs" the rest of the stack (line 20). We go into this operation in more detail in §4.5. Afterwards, the algorithm creates a new node for the next hop v with the new partial equivalence class $\mathcal{H}_{i_j}$ and the new stack σ' (line 20).

At this point the algorithm marks u as visited (line 22) checks if the new node creates an infinite loop (line 25). The details of this check are complex and are covered in detail in §5.1. Finally, if the new node v has not yet been visited, it recursively calls Dfs from this new node (line 28).

Example. We can see an application of Algorithm 1 in Figure 4. This shows the DFS trace produced for the earlier example network shown in Figure 3 that uses a time-to-live field. The execution is shown for the partial equivalence class $\mathcal{H}_i = (2)$, which corresponds to packets in the set $H_0 = \phi_{dst}(10.7.1.0/24) \cap \phi_{ttl}(\{1, .., 255\})$. Initially the algorithm starts in partial equivalence class (2) with the stack $\varepsilon \cdot H_0$. From here, the algorithm discovers that the next hop is v_2 and the transformation is $\tau_{push} \circ \tau_{ttl}$. The result of applying this transformation to $\varepsilon \cdot H_0$ is two new sets of stacks corre-

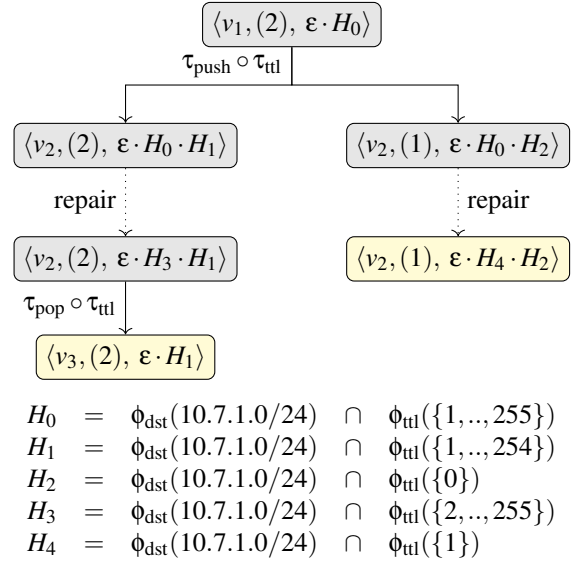
$$H_3 = \phi_{\text{dst}}(10.7.1.0/24) \cap \phi_{\text{ttl}}(\{2,..,255\})$$
$$H_4 = \phi_{\text{dst}}(10.7.1.0/24) \cap \phi_{\text{ttl}}(\{1\})$$


Figure 4: Example execution of Algorithm 1 for the partial equivalence class $\mathcal{H}_i = (2)$ from the example in Figure 3.

sponding to different partial equivalence classes. The first is $\varepsilon \cdot H_0 \cdot H_1$, which remains in partial equivalence class (2). The second is $\varepsilon \cdot H_0 \cdot H_2$, which now falls into partial equivalence class (1) since the TTL field reaches zero. In both cases, we "repair" the stack since the first header may be wrong. The results are given by $\varepsilon \cdot H_3 \cdot H_1$ and $\varepsilon \cdot H_4 \cdot H_2$. Those packets in partial equivalence class (1) are now dropped since the TTL field is 0. And the remaining packets are forwarded to v_3, decapsulated, and eventually delivered.

4.5 Repairing the stack

Recall in the example in Figure 4, the initial state is $\langle v_1, (2), H_0 \rangle$ capturing all packets for the destination pre-

fix with TTL greater than zero. After being transformed by $\tau_{\text{push}} \circ \tau_{\text{ttl}}$, the resulting headers for partial equivalence class (2) are given by the stack $\varepsilon \cdot H_0 \cdot H_1$. Regrettably, H_0 is no longer correct because it contains a packet with a TTL field of 1, which would be 0 after the TTL decrement and thus no longer be part of H_1, which has TTL values in $\{1,..,254\}$.

The problem generally is that after restricting the top of the stack (Algorithm 1, line 17), the bottom of the stack may contain too many headers. To repair the stack, we reverse all transformations applied to the current stack to recover the initial set of packets from the source that will eventually lead to the new restricted stack. We then replay the transformations forward with the correct initial set to simulate the construction

of the repaired stack as though we had started with the set that takes into account the later restriction.

Definition 4.4 (Transformation Inverse). *Given a transformation τ for sets of stacks, we define its inverse as $\tau^{-1}(H^*) = \{\sigma \in \mathcal{H}^* \mid \tau(\sigma) \in H^*\}$.*

Assume we have a sequence of stacks and transformations starting from the initial state of the depth-first search: $\sigma_1 \xrightarrow{\tau_1} \sigma_2 \xrightarrow{\tau_2} \ldots \sigma_{n-1} \xrightarrow{\tau_{n-1}} \sigma_n$. We compute:

$$
\begin{aligned}
\sigma_{\text{init}} &= (\tau_1^{-1} \circ \ldots \circ \tau_n^{-1})(\sigma_n) \\
\sigma_{\text{repair}} &= (\tau_n \circ \ldots \circ \tau_1)(\sigma_{\text{init}})
\end{aligned}
$$

Example. We clarify this idea through an example. In the DFS shown in Figure 4, at node $\langle v_2, (2), H_0 \cdot H_1 \rangle$ we perform a stack repair operation. To do so, we compute σ_{init}:

$$
\begin{aligned}
& \sigma_{\text{init}} && \textit{compute } \sigma_{\text{init}} \\
=\ & (\tau_{\text{push}} \circ \tau_{\text{ttl}})^{-1}(H_0 \cdot H_1) && \textit{unfold definition} \\
=\ & \tau_{\text{push}}^{-1}(\tau_{\text{ttl}}^{-1}(H_0 \cdot H_1)) && \textit{function composition} \\
=\ & \tau_{\text{push}}^{-1}(H_0 \cdot H_3) && \textit{inverse of } \tau_{\text{ttl}} \\
=\ & H_3 && \textit{inverse of } \tau_{\text{push}}
\end{aligned}
$$

$$
\begin{aligned}
& \sigma_{\text{repair}} && \textit{compute } \sigma_{\text{repair}} \\
=\ & (\tau_{\text{push}} \circ \tau_{\text{ttl}})(H_3) && \textit{unfold definition} \\
=\ & \tau_{\text{ttl}}(\tau_{\text{push}}(H_3)) && \textit{function composition} \\
=\ & \tau_{\text{ttl}}(H_3 \cdot H_3) && \textit{definition of } \tau_{\text{push}} \\
=\ & H_3 \cdot H_1 && \textit{definition of } \tau_{\text{ttl}}
\end{aligned}
$$

This result is given by node $\langle v_2, (2), H_3 \cdot H_1 \rangle$ in Figure 4.

4.6 Property expressiveness

For efficiency, our algorithm concerns itself primarily with checking path properties P that are "subpath closed":

Definition 4.5 (Subpath Closed). *A property P is subpath closed if whenever P holds on a sequence of nodes $u_0, \ldots, u_n$, it also holds on any subsequence $u_j, u_{j+1}, \ldots, u_n$ for $j \geq 0$.*

Subpath-closed properties include reachability to a destination, loop-freedom, and network isolation. We focus on this subset of properties because they permit an efficient implementation by avoiding exploring previously visited nodes (Algorithm 1, line 5). However, this is not an inherent limitation of our algorithm – with only minor changes it can be used to check any path properties for packets, albeit at greater cost since we can not reuse previously visited nodes.

5 Algorithm Correctness

We now prove that Algorithm 1 is sound with respect to our concrete packet semantics from §3.3. But first we must define what it means for a DFS state to contain a located packet:

Definition 5.1 (DFS overapproximation). *For a located packet ℓ and Dfs node u, we write $\ell \in u$ if $\ell = \langle v, \sigma \rangle$ and $u.\text{loc} = v$ and $\sigma \in u.\text{stack}$ and $\text{top}(\sigma) \in u.\text{ec}$.*

rule	p	e	m	τ

Figure 5: Example network with an infinite loop for the 10.0.1.1 address. The value d can be any other IP address.

Now given this definition, we state the soundness of Algorithm 1 as follows by relating the concrete semantics to the DFS calls made in the algorithm. For the simplicity of the proof, we elide the visited set optimization (lines 5 and 27) and the loop check (line 25). We revisit the loop check for termination in §5.1

Theorem 5.1 (Soundness). *For any network $\mathcal{N}$, partial equivalence class $\mathcal{H}_j$, node v, header $h \in \mathcal{H}_j$, located packet $\ell = \langle v, \varepsilon \cdot h \rangle$, and step $i \geq 0$, if not $\mathcal{N} \otimes \langle i, \ell \rangle$ then after calling $\text{CheckProperty}(\mathcal{N}, \mathcal{H}_j, \{v\}, P)$ there will eventually be a call to $\text{Dfs}(\mathcal{N}, P, \_, u, i)$ for some node u such that $\text{top}(\llbracket \mathcal{N} \rrbracket_i \ell) \in u$.*

Proofs are included as extra material in the appendix.

Corollary 5.1 (Property checking). *If i is the smallest step such that $\mathcal{N} \otimes \langle i, \ell \rangle$ then Algorithm 1 checks $P(u)$ for some DFS node u such that $\text{top}(\llbracket \mathcal{N} \rrbracket_i \ell) \in u$.*

5.1 Infinite Loops and Termination

While Theorem 5.1 says that Algorithm 1 is sound, it says nothing about whether it will terminate. Intuitively, a network $\mathcal{N}$ contains a loop for a header h, whenever that packet will visit a node infinitely often in the future[2]. Catching infinite loops is vital since otherwise Algorithm 1 may not terminate. Finding loops in layered networks is surprisingly challenging since the space of header stacks is infinite and no stack need repeat to have an infinite loop.

We start by defining a loop for a given header:

Definition 5.2 (Network Loop). *Given a network $\mathcal{N}$, an input located packet ℓ induces a loop if there exists a step index $i \in \mathbb{N}$ for the start of the loop such that for all steps $j \in \mathbb{N}$ where $j \geq i$, there exists a future $k \in \mathbb{N}$ such that:*

$$
\begin{aligned}
& (1) && |\llbracket \mathcal{N} \rrbracket_j \ell| < |\llbracket \mathcal{N} \rrbracket_k \ell| \\
& (2) && \text{top}(\text{hops}(\llbracket \mathcal{N} \rrbracket_j \ell)) = \text{top}(\text{hops}(\llbracket \mathcal{N} \rrbracket_k \ell))
\end{aligned}
$$

---

[2]Note: networks modeling the TTL field like in Figure 7 do not have a loop in the algorithmic sense because the packet will eventually expire after a finite number of steps. Such issues can be caught with an appropriate property P that looks for packets that eventually expire with TTL 0.

In other words, a loop exists if beyond some point in the trace (*i*) the trace will continue to grow forever and repeatedly visit the same nodes in the network.

Example. We demonstrate the difficulty of detecting infinite loops in Figure 5. Unlike in single layer networks, loops in multi-layer networks may be transient even when the top of the stack repeats at the same node because of implicit state lower in the header stack. Further, any given stack may not repeat even when an infinite loop exists since the stack can keep growing. Consider a trace for the example in Figure 5 for traffic sent from u_1 with the 10.0.1.1 destination.

$\langle u_1, 10.0.1.1 \rangle$	*encapsulate twice*
$\langle u_2, 10.0.1.1 \cdot d \cdot d \rangle$	*pop*
$\langle u_2, 10.0.1.1 \cdot d \rangle$	*pop*
$\langle u_2, 10.0.1.1 \rangle$	*forward to u_3*
$\langle u_3, 10.0.1.1 \cdot 10.0.1.1 \rangle$	*forward to u_2*
$\langle u_2, 10.0.1.1 \cdot 10.0.1.1 \cdot 10.0.1.1 \rangle$	*forward to u_3*
$\ldots$	

Note that the top of stack d is repeated at node u_2, however, this is not the cause of the infinite loop since eventually this outer header is removed and the forwarding proceeds according to the inner header for the 10.0.1.1 address. Later, however, there is an infinite loop despite the stack never repeating exactly at any node in the trace.

Necessary and sufficient conditions. Suppose we have a current header stack $\sigma \cdot h$ at node u, and later on we arrive at u once more, but with header stack $\sigma \cdot \sigma' \cdot h$ with the same shared prefix σ. Moreover, assume that between visiting u twice, the rules never examine the contents of σ. If these conditions hold then the top of the stack h "regenerates" itself without needing context from σ. In this case, we can infer that there will be an infinite loop at u given by: $\langle u, \sigma \cdot h \rangle \longrightarrow \langle u, \sigma \cdot \sigma' \cdot h \rangle \longrightarrow \langle u, \sigma \cdot \sigma' \cdot \sigma' \cdot h \rangle \longrightarrow \ldots$ This idea is similar to repeating heads from the verification of pushdown systems [36] and we prove that this condition is both sufficient and necessary for a permanent loop:

Theorem 5.2 (Loop conditions). *Given a network $\mathcal{N}$ over $\mathcal{H}^*$, an input ℓ induces a loop if and only if there exists $i, k \in \mathbb{N}$, $\sigma, \sigma' \in \mathcal{H}^*$, and $h \in \mathcal{H}$ such that:*

(1) $\mathrm{top}(\llbracket \mathcal{N} \rrbracket_i \ell) = \langle u, \sigma \cdot h \rangle$
(2) $\mathrm{top}(\llbracket \mathcal{N} \rrbracket_k \ell) = \langle u, \sigma \cdot \sigma' \cdot h \rangle$
(3) $\forall j, \ i < j < k \Rightarrow \exists v, \sigma'', \ \mathrm{top}(\llbracket \mathcal{N} \rrbracket_j \ell) = \langle v, \sigma \cdot \sigma'' \rangle$

Loop detection algorithm. Based on the insights from Theorem 5.2, we develop an efficient procedure for checking loops during traversal, which is described in Algorithm 2. Given the current node (*u*) in the DFS, and the visited nodes (visited) the procedure checks for a loop by looking up all candidate nodes (C) for the same current topology location (*u*.loc, line 2). The algorithm walks backwards through the current path (line 5) and computes the longest common suffix (LCS) γ between the tops of the stacks for the two nodes u

```
1   // instantiate a new network verifier
2   var headerType = new HeaderType(
3       ("dstip", 32), ("srcip", 32));
4   var nv = new NetworkVerifier(headerType);
5
6   // build the network topology
7   var (n1, n2) = nv.GetOrAddNodes("n1", "n2");
8   var (e12, e21) = nv.GetOrAddBiEdge(n1, n2);
9
10  // register the properties we want to monitor
11  nv.AddCheck(new LoopCheck(nv.AllHeaders()));
12
13  // create new prioritized forwarding rules
14  var r = nv.CreateRange(
15      (10, 20), (0, uint.MaxValue));
16  var t = nv.Seq(nv.Push(), nv.Set("dstip", 10));
17  var rule1 = new Rule(100, e12, r, t);
18  var rule2 = new Rule(100, e21, r, nv.Pop());
19
20  // find violations from adding rules.
21  var violations1 = nv.AddRule(rule1);
22  var violations2 = nv.AddRule(rule2);
23  Assert.AreEqual(1, violations2.Count);
```

Figure 6: Example use of the KATRA verification API.

and c (line 9) while also tracking the minimum stack size μ between the two nodes. If μ is greater than $|c.\mathrm{stack}| - \gamma$ (where γ generalizes h in the loop conditions) then there is a loop (line 11). If the set of candidate loop nodes has been exhausted, the algorithm terminates early.

6 Implementation

We have built an incremental verification system, KATRA for layered networks based on the idea presented. KATRA is implemented as a C# library and is written in around 8K lines of code. KATRA's implementation for computing header equivalence classes is based on the algorithm from [46], but is modified to incrementally compute the *minimal* set of partial equivalence classes (see §4.2). An example of an API for the tool is shown in Figure 6. The tool is programmable and is parameterized by the format of the header (e.g., MPLS vs. IPv4) that the user wants to check (line 1)[3]. Our implementation extends §3.2 to support mulipath routing.

Optimizations. KATRA makes use of several optimizations to scale. One key challenge is that the use of partial equivalence classes (§4.2) means that we must find overlapping equivalence classes during traversal (Algorithm 1, line 16). To make this operation fast, for every packet set H we keep a pair of $\langle b, H \rangle$ where H is the set itself modeled as a BDD [10], and b is a multi-dimensional bounding box that overapproximates

---

[3]To model different headers in different layers (e.g., Ethernet and IPv4 headers), one can define a "master" header with the union of fields across headers along with a field indicating which header is currently being used.
Figure 7: Example of a layered benchmark network with layers $\ell = 2$ and nodes $n = 5$.

the set of headers in H. When sets are unioned or intersected, the corresponding bounding boxes are grown or shrunk to remain safe overapproximations for the sets of headers.

Keeping bounding boxes for header sets allows for the use of fast collision detection data structures. We leverage bounding volume hierarchies [40], which are hierarchical balanced trees of bounding volumes used in game engines to quickly eliminate possible collisions.

Our implementation also examines header sets H and determines if the fields lie on prefix boundaries (e.g., for IPv4 prefix-based forwarding). If so, it uses an optimized trie data structure to accelerate the collision detection.

7 Evaluation

We are primarily interested in evaluating the performance of KATRA relative to a straightforward extension of prior work that models packets with a fixed (bounded) number of headers N. Of course, this approach requires a user to specify N and may be unsound when N is not large enough to handle the maximum stack possible in the network. However, if N is chosen carefully this provides a reasonable comparison point.

7.1 Different implementations

To compare the approach in KATRA with that of duplicate headers (DUP), we instantiate our framework (§6) with two types of headers. For DUP, we instantiate the verifier with a header that is similar to that of Figure 6 (line 2) but extended to a full IPv4 header, and replicated N times. We choose N to account for the maximum amount of layering in each benchmark and do not evaluate DUP on networks that contain unbounded loops, since it will give incorrect results.

Each field in the DUP header has versions f_1 to f_N and f_1 represents the outermost header (top of stack). The push operation is implemented by copying each field f_i to f_{i+1}, its next layer version, and the bottom header is lost in the process if the stack exceeds size N. The pop operation is implemented similarly by copying each field f_{i+1} to f_i.

Single layer performance. APKeep was demonstrated to outperform prior incremental verifiers while also being more

robust to multi-dimensional rules [46]. However, since APKeep is not open source, we instead use our implementation of KATRA, which uses a similar base algorithm to compare results. We ran KATRA on the same datasets reported on in the APKeep paper and originally released by Deltanet [20]. We found the performance for these single layer networks to be similar to the times reported on by APKeep, and as such do not report on the results here. Since the implementation performance is comparable, going forward we report only the times from different instantiations of KATRA.

Moreover, instantiating DUP in KATRA allows us to directly compare our algorithm to a naive solution without other factors coming into play. For example, DUP also makes use of our partial equivalence class reduction, our fast collision detection data structure, and other optimizations.

7.2 Performance on multilayer networks

To measure the performance of KATRA for multilayer networks (i.e., with stack size greater than 1), we generated a parameterized set of benchmark networks.

Benchmark description. The benchmarks have two parameters: the number of layers ℓ in the network, and the number of nodes per layer n. The first layer represents the physical network, while each layer $i > 1$ represents an overlay network built on top of layer $i-1$. Each link in the layer i in the network is implemented by encapsulating a packet and forwarding it according to the destination prefix for the tunnel endpoint in layer $i-1$. Routing in each layer is configured to announce and propagate routes along shortest paths. For each $\langle \ell, n \rangle$ pair, we generate the topologies as random connected graphs and map nodes in each overlay to nodes in the underlay for the purpose of establishing tunnel endpoints.

An example of such a network with $\ell = 2$ and $n = 5$ is shown in Figure 7. In the example, to forward traffic between layer 2 nodes b and e, traffic is encapsulated and forwarded from i to f via h in layer 1. For such networks, there are a total of $O(\ell \cdot n^2)$ forwarding rules.

The first property we check is reachability between all source and destination nodes in the outermost layer ℓ for all advertised subnets. This strategy forces KATRA to reason about the forwarding behavior at every single layer. Because these reachability properties are violated while tunnels are being established at different layers, for this benchmark we disable property checking while connectivity is not expected.

Performance of KATRA ***compared to*** DUP. We show the total verification time of KATRA and DUP in Figure 8 and Figure 9. Figure 8 shows the total time spent recomputing partial equivalence classes for both approaches. KATRA is faster than DUP because DUP must represent significantly larger headers in order to capture the full stack. This leads to larger packet set representations in the BDD library and more expensive set and transform operations.

Similarly, Figure 9 shows the total time spent checking
Figure 8: Total time spent recomputing partial equivalence classes for an approach based on duplicate headers DUP vs. KATRA.
Figure 9: Total time spent checking end-to-end reachability for an approach based on duplicate headers DUP vs. KATRA.

reachability for KATRA and DUP. There is a similar trend, with KATRA's decomposed stack set representation leading to a large speedup over that of DUP. In both cases, the speedup of KATRA grows with both the number of layers ℓ and the number of nodes per layer n in the graph. For instance, at $\ell = 6$ and $n = 100$, property checking is nearly 50x faster.

KATRA *rule update time*. The total verification time grows quickly in part because the number of rules needed to implement the network design is proportional to the square of the size of the network. However, looking at the time for each individual rule update in Figure 10, essentially all updates execute in under 1ms. The graphs show the CDF for rule insertion time in milliseconds. In particular, the insertion time is relatively independent of ℓ yet increases slightly with n.

7.3 Performance of loop checking

To evaluate the performance of Algorithm 2, we used example networks with $\ell = 2$ and replaced the reachability checks for each destination subnet with a single loop check for all packets. Unlike with reachability, this property gets rechecked after every single rule insertion. Since each link in layer 2 crosses many of the same previous nodes in layer 1, this forces Algorithm 2 to check for potential loops frequently.

A CDF of the rule insertion and loop checking time for each update are shown in Figure 11. We vary n from 20 to 80 in increments of 20 and compare the results. Figure 11a shows the checking time when rules are inserted in an arbitrary order. The time grows with the size of the network and can become high at the tail (e.g., around 40ms).

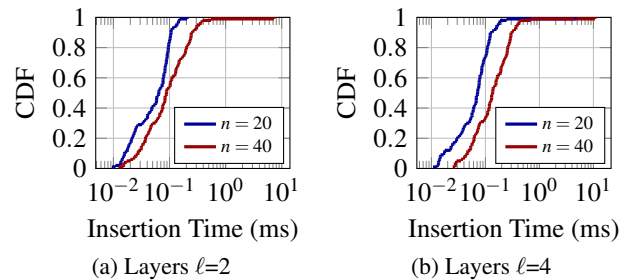
The reason why is that if a rule r with transformation τ_{pop} is inserted early, then every other rule insertion will affect the partial equivalence class for r. In other words, after a decapsulation a packet may now be in any partial equivalence


Figure 10: CDF of rule insertion time for (a) ℓ=2 and (b) ℓ=4. Both show results for nodes per layer $n = 20$ and $n = 40$.

class, so when any other partial equivalence class changes, the partial equivalence class for r must also be rechecked. At the extreme, this means that every rule insertion can require rechecking the entire network from scratch. This is inherent in the problem and is not unique to KATRA (e.g., APKeep suffers a similar blowup for these networks).

However, by slightly reordering rule updates, we can improve the performance significantly. In Figure 11b, we show the same results but where the rule insertion order is done in a way to delay the insertion of decapsulation rules. From the figure, we can see that in the latter case, the checking time remains well below 1ms for nearly all rules.

Since this benchmark requires checking the loop property after *all* rule updates, the performance improvement of KATRA grows substantially over that of DUP. Figure 12 shows the total time to verify the loop-free property for all rules updates. It shows the performance for $\ell = 2$ layers where we cap the total verification time at 4 minutes. DUP times out after $n = 100$ with 20K rules while KATRA can verify networks up to $n = 300$ with 180K rules. The relative speedup of KATRA over DUP for $n = 20$ to $n = 100$ is shown in Figure 12b.

(a) Random order (b) Delayed decap
Figure 11: CDF of rule insertion time for $\ell=2$ and $n = 20$ to $n = 80$ in increments of 20. Total checking time for loops is low when decapsulation rule insertion is delayed.

(a) Total time (b) Relative speedup
Figure 12: (a) Total verification time for DUP (blue) vs. KATRA (red) for $\ell = 2$ when checking for forwarding loops on every change. (b) Speedup ranges from 5x to 32x.

8 Related Work

KATRA is related to several threads of prior work:

Data plane verification. There is a long line of work on data plane verification, starting from the seminal work of Xie et. al. [27, 41, 42], and incremental verification starting with Veriflow [20, 26, 29, 46]. Most work on data plane verification has assumed stateless and transformation-free forwarding, with the exception of AP [42] and APKeep [46], which handle transformations (see §4). However, none of these works consider *layered* networks where encapsulation and decapsulation are pervasive. AP and APKeep can model finite header stacks (e.g., DUP from §7) but this approach can be unsound and can have poor performance, particularly when encapsulation is common. KATRA builds on prior work to enable incremental verification with transformations and layering.

Layered network verification. There has been little work on verifying multilayer networks. One related work in this area is Tiramisu [2], which can verify some combinations of layer 2 and 3 control plane routing protocols (e.g., BGP, iBGP, OSPF). However, Tiramisu is only superficially related to KATRA: (i) Tiramisu verifies control plane routing while KATRA verifies data plane forwarding, (ii) Tiramisu focuses on specific layering mechanisms (e.g., between iBGP and eBGP) while KATRA focuses on arbitrarily layered *data planes*, and (iii) KATRA is interested in *real-time* (millisecond) verifica-

tion time for incremental changes.

Recent works on verifying MPLS label switching with fast failover [22–24] were the first to leverage the insight that label-based forwarding can be viewed as pushdown automata. The works use polynomial time algorithms to answer reachability questions for all possible failures using overapproximation. While they focus on reasoning about failures, we similarly leverage this insight that ideas from pushdown automata are useful for reasoning about stacks of headers. We generalize this reasoning from concrete label-based forwarding to symbolic forwarding (e.g., prefix-based forwarding) and also focus on *realtime* verification for changes.

There are significant differences in the actual algorithms. These prior works use saturation-based procedures to iteratively compute automata representations of (backward or forward) reachable configurations of the pushdown system. In contrast, our algorithm is an on-the-fly depth-first search over *symbolic* configurations, which include (partial) equivalence classes over the header space.

One work [24] considers abstractions based on network labels to reduce PDS size and proposes a CEGAR-style refinement procedure, which improves performance in many practical examples. Our symbolic configurations are also *abstractions* of the network state space, where the control state is a partial equivalence class in the header space located at a particular node in the network, and the stack is a word over these classes. These abstractions are refined lazily on-the-fly in our novel method for stack repair, such that any trace in our algorithm follows the specified network semantics.

Model checking of pushdown systems. More broadly, our work builds on prior work in model checking of pushdown systems [6, 9, 36], which can naturally represent sequential programs with recursive procedures. Similar to symbolic procedures for pushdown systems [12, 36], we also utilize BDDs [11] for efficient representation of the state space and use a notion similar to *repeating heads* [36] for detecting loops. However, rather than computing sets of reachable configurations, our procedure performs on-the-fly verification to soundly check reachability of located packets.

9 Conclusion

In this paper we have presented KATRA, the first real-time verifier for *layered* networks. KATRA extends incremental data-plane verification to the setting with unbounded header stacks. To do so, we introduced a new network model for layered networks and presented an efficient algorithm for such networks. The algorithm leverages a new idea of *partial* equivalence classes and keeps a decomposed symbolic stack representation that it lazily "repairs" as needed. Comparing KATRA against a solution based on header duplication, we showed that KATRA is 5x-32x faster for just 2 layers, and that its benefits grow with network size and layering.

Appendix

Theorem 5.1 (Soundness). *For any network $\mathcal{N}$, partial equivalence class $\mathcal{H}_j$, node v, header $h \in \mathcal{H}_j$, located packet $\ell = \langle v, \varepsilon \cdot h \rangle$, and step $i \geq 0$, if not $\mathcal{N} \otimes \langle i, \ell \rangle$ then after calling* CheckProperty$(\mathcal{N}, \mathcal{H}_j, \{v\}, P)$ *there will eventually be a call to* Dfs$(\mathcal{N}, P, \_, u, i)$ *for some node u such that* top$(\llbracket \mathcal{N} \rrbracket_i \ell) \in u$.

Proof. The proof is by induction on the step i. For the sake of simplicity, we assume that lines 5 and 27 of Algorithm 1, which are optimizations using the visited set, are removed for the remainder of the proof.

Base case ($i = 0$) By assumption we have $\ell = \langle v, \varepsilon \cdot h \rangle$. From unfolding the definition of the semantics $\llbracket \mathcal{N} \rrbracket$ for the ($i = 0$) step, we obtain the following equality:
$$\text{top}(\llbracket \mathcal{N} \rrbracket_0 \ell) = \text{top}(\varepsilon \cdot \ell) = \ell = \langle v, \varepsilon \cdot h \rangle$$
Thus we must prove that there is a call to Dfs$(\mathcal{N}, P, \_, u, 0)$ such that $u.\text{loc} = v$ and $\varepsilon \cdot h \in u.\text{stack}$ and top$(\varepsilon \cdot h) \in u.\text{ec}$. This trivially follows from line 7 of Algorithm 1. Since $S = \{v\}$ (line 3), we see that $s = v$ (line 3) and therefore $u.\text{loc} = v$ as expected, and $u.\text{stack} = \varepsilon \cdot \mathcal{H}_j$ (line 4), which implies that $\varepsilon \cdot h \in u.\text{stack}$ since $\varepsilon \cdot h \in \varepsilon \cdot \mathcal{H}_j \iff h \in \mathcal{H}_j$ by definition and this is an assumption. Finally, we have that top$(\varepsilon \cdot h) = h \in u.\text{ec}$ or $h \in \mathcal{H}_j$ again by assumption.

Inductive case ($i > 0$) The proof proceeds by using the inductive hypothesis for step $i - 1$ to prove that the statement holds for step i. We list out our assumptions from the proof statement as well as the induction hypothesis below:

- not $\mathcal{N} \otimes \langle i, \ell \rangle$
- not $\mathcal{N} \otimes \langle i - 1, \ell \rangle$
- top$(\llbracket \mathcal{N} \rrbracket_i \ell) = \langle v_1, \sigma_1 \rangle$
- top$(\llbracket \mathcal{N} \rrbracket_{i-1} \ell) = \langle v_2, \sigma_2 \rangle$
- there was a call to Dfs$(\mathcal{N}, P, \_, u_2, i - 1)$ for some u_2
- $u_2.\text{loc} = v_2$
- $\sigma_2 \in u_2.\text{stack}$
- top$(\sigma_2) \in u_2.\text{ec}$

Given these assumptions, we must prove that each of the following statements holds as a result:

- there is a call to Dfs$(\mathcal{N}, P, \_, u_1, i)$ for some u_1
- $u_1.\text{loc} = v_1$
- $\sigma_1 \in u_1.\text{stack}$
- top$(\sigma_1) \in u_1.\text{ec}$

We walk through the lines of code in Algorithm 1 starting from the call to Dfs$(\mathcal{N}, P, \_, u_2, i - 1)$ that we know must have taken place. By our assumption that top$(\sigma_2) \in u_2.\text{ec}$, and from the definition of a partial equivalence class (same local forwarding for all packets in the equivalence class), we know the $\langle \text{edge}, \tau \rangle$ pair returned in line 11 must be equivalent to those of the semantics: $\tau = \text{modify}(\Omega(v_2, \sigma_2))$ and $\text{edge} = \text{edge}(\Omega(v_2, \sigma_2))$ from the semantic definition in §3.3. Evaluating $\llbracket \mathcal{N} \rrbracket_i \ell$ there are two cases:

Case 1: if $\tau(\sigma_2)$ is undefined, then we compute: $\llbracket \mathcal{N} \rrbracket_i \ell = \llbracket \mathcal{N} \rrbracket_{i-1} \ell$ and we observe that $\mathcal{N} \otimes \langle i - 1, \ell \rangle$. In this case, the algorithm executes line 14 and terminates. Note that we do not call Dfs again, however, in this case the semantics were terminated at step $i - 1$ which contradicts the assumptions. Further, note that this is the minimal time step i at which $\mathcal{N} \otimes \langle i, \ell \rangle$ since we assumed not $\mathcal{N} \otimes \langle i - 1, \ell \rangle$.

Case 2: if $\tau(\sigma_2)$ is defined, then we compute
$$\langle v_1, \sigma_1 \rangle = \text{top}(\llbracket \mathcal{N} \rrbracket_i \ell) = \text{top}(\llbracket \mathcal{N} \rrbracket_{i-1} \ell \cdot \langle \text{tgt}(\text{edge}), \tau(\sigma_2) \rangle) = \langle \text{tgt}(\text{edge}), \tau(\sigma_2) \rangle$$

By the definition of τ lifted to sets, we know that because $\sigma_2 \in u.\text{stack}$ then it follows that $\tau(\sigma_2) \in \tau(u.\text{stack})$ (line 12) and therefore $\sigma_1 \in \tau(u.\text{stack})$. The algorithm proceeds on line 16 to iterate over all partial equivalence classes that can intersect $\tau(u.\text{stack})$. Because partial equivanence classes are disjoint and complete (see §4.2), there will be exactly one such $\mathcal{H}_{j_k}$ such that top$(\sigma_1) \in \mathcal{H}_{j_k}$. From this we can deduce line 17 will compute a new set of stacks σ' that must contain σ_1 – that is $\sigma_1 \in \sigma'$ by construction.

Line 19 of the algorithm updates σ' as Repair(σ'). Because $\sigma_1 \in \sigma'$ we must show that that $\sigma_1 \in \text{Repair}(\sigma')$ as well. To compute Repair(σ') we first compute $(\tau_1^{-1} \circ \ldots \circ \tau_n^{-1})(\sigma')$, which is equivalent to $\sigma_{\text{init}} = \{\sigma'' \mid (\tau_n \circ \ldots \circ \tau_1)(\sigma'') \in \sigma'\}$. Since σ_1 is the result

of applying $(\tau_n \circ \ldots \circ \tau_1)$ to the initial header $\varepsilon \cdot h$, it follows that $\varepsilon \cdot h \in \sigma_{\text{init}}$. Because $\text{Repair}(\sigma') = \sigma_{\text{repair}} = (\tau_n \circ \ldots \circ \tau_1)(\sigma_{\text{init}})$ and because $\varepsilon \cdot h \in \sigma_{\text{init}}$, it follows that $(\tau_n \circ \ldots \circ \tau_1)(\varepsilon \cdot h) \in (\tau_n \circ \ldots \circ \tau_1)(\sigma_{\text{init}})$ and therefore $(\tau_n \circ \ldots \circ \tau_1)(\varepsilon \cdot h) \in \text{Repair}(\sigma')$.

Finally from lines 20 and 21 a new nexthop is added to the set of nexthops that contains the node u_1 where $u_1.\text{loc} = \text{tgt}(\text{edge})$ and $u_1.\text{ec} = \mathcal{H}_{j_k}$ and $u_1.\text{stack} = \sigma'$. Line 23 iterates over the nexthops and calls Dfs on line 28 with this new node.

To complete the proof, we put together the pieces to show that the 4 conditions above hold.

- line 28 calls $\text{Dfs}(\mathcal{N}, P, \_, u_1, i)$ for the u_1 described previously
- we know that $u_1.\text{loc} = \text{tgt}(\text{edge}) = v_1$
- we know that $\sigma_1 \in u_1.\text{stack}$ because $\sigma_1 \in \sigma'$ and $\sigma' = u_1.\text{stack}$
- we know that $\text{top}(\sigma_1) \in u_1.\text{ec}$ because $\text{top}(\sigma_1) \in \mathcal{H}_{j_k}$ and $u_1.\text{ec} = \mathcal{H}_{j_k}$

$\square$

Corollary 5.1 (Property checking). *If i is the smallest step such that $\mathcal{N} \otimes \langle i, \ell \rangle$ then Algorithm 1 checks $P(u)$ for some DFS node u such that $\text{top}(\llbracket \mathcal{N} \rrbracket_i \ell) \in u$.*

Proof. The proof follows directly from Theorem 5.1. At the $i - 1$ step, we know that there must have been a call to $\text{Dfs}(\mathcal{N}, P, \_, u, i - 1)$ for some u such that $\text{top}(\llbracket \mathcal{N} \rrbracket_{i-1} \ell) \in u$ From the proof we can see that the algorithm will proceed to line 14, where it will check $P(u)$. $\square$

Theorem 5.2 (Loop conditions). *Given a network $\mathcal{N}$ over $\mathcal{H}^*$, an input ℓ induces a loop if and only if there exists $i, k \in \mathbb{N}$, $\sigma, \sigma' \in \mathcal{H}^*$, and $h \in \mathcal{H}$ such that:*

$$
\begin{aligned}
&(1) \quad \text{top}(\llbracket \mathcal{N} \rrbracket_i \ell) = \langle u, \sigma \cdot h \rangle \\
&(2) \quad \text{top}(\llbracket \mathcal{N} \rrbracket_k \ell) = \langle u, \sigma \cdot \sigma' \cdot h \rangle \\
&(3) \quad \forall j, \, i < j < k \Rightarrow \exists v, \sigma'', \, \text{top}(\llbracket \mathcal{N} \rrbracket_j \ell) = \langle v, \sigma \cdot \sigma'' \rangle
\end{aligned}
$$

Proof. First, we require that no rule transformations τ ever both pop and push in the same transformation. For instance, the transformation $\tau_{\text{pop}} \circ \tau_{\text{push}}$ is disallowed, whereas $\tau_{\text{push}} \circ \tau_{\text{push}}$ is allowed. Note that this does not change the expressive power of KATRA since one can always separate such a transformation into multiple transformations across nodes to get the same effect.

Sufficient ($\Leftarrow$) Assume that the conditions (1), (2), and (3) above hold. We must prove that ℓ induces a loop. From (1) and (2), we know that there is a trace for $\llbracket N \rrbracket_k \ell$ to step k of the form:

$$
\underbrace{\langle u_1, \sigma_1 \rangle}_{\text{step 1}} \to \underbrace{\langle u_2, \sigma_2 \rangle}_{\text{step 2}} \to \ldots \to \langle u_{i-1}, \sigma_{i-1} \rangle \to \underbrace{\langle u, \sigma \cdot h \rangle}_{\text{step } i} \to \underbrace{\langle u_{i+1}, \sigma_{i+1} \rangle \to \langle u_{i+2}, \sigma_{i+2} \rangle \to \ldots}_{\text{steps } i < j < k} \to \underbrace{\langle u, \sigma \cdot \sigma' \cdot h \rangle}_{\text{step } k}
$$

We observe that from (1), (2), (3), the stack retains the prefix σ for all steps between i and k. From the assumption that transformations don't both push and pop the stack, and our model requirement that transformations can only match the top of the stack, this means that the forwarding for the stack at these steps does not depend on σ, and thus forall σ the subtrace starting at step i:

$$
\underbrace{\langle u, \sigma \cdot h \rangle}_{\text{step } i} \to \underbrace{\langle u_{i+1}, \sigma_{i+1} \rangle \to \langle u_{i+2}, \sigma_{i+2} \rangle \to \ldots}_{\text{steps } i < j < k} \to \underbrace{\langle u, \sigma \cdot \sigma' \cdot h \rangle}_{\text{step } k}
$$

would be the same for any such σ. For this reason, expanding out the trace from k steps to $2k - i$ steps, we observe the following continuation of the original trace:

$$
\underbrace{\langle u, \sigma \cdot h \rangle}_{\text{step } i} \to \underbrace{\langle u_{i+1}, \sigma_{i+1} \rangle \to \langle u_{i+2}, \sigma_{i+2} \rangle \to \ldots}_{\text{steps } i < j < k} \to \underbrace{\langle u, \sigma \cdot \sigma' \cdot h \rangle}_{\text{step } k} \to \ldots \to \underbrace{\langle u, \sigma \cdot \sigma' \cdot \sigma'' \cdot h \rangle}_{\text{step } 2k-i}
$$

In other words, because the forwarding between steps i and k did not depend on σ, it similarly will not depend on $(\sigma \cdot \sigma')$ for the same top of stack h between steps k and $k + (k - i) = 2k - i$ for the same loop interval. Moreover, we know that $\sigma'' = \sigma'$. This same reasoning applies inductively with the new prefix $(\sigma \cdot \sigma' \cdot \sigma')$. Thus we have an infinite loop.

Necessary ($\Rightarrow$) Let us assume there is an input ℓ that induces a loop in the network $\mathcal{N}$. We must prove that there exist $i, k \in \mathbb{N}$ and $\sigma, \sigma' \in \mathcal{H}^*$ and $h \in \mathcal{H}$ such that conditions (1), (2), and (3) hold. By way of contradiction, we assume ℓ induces a loop in $\mathcal{N}$ but that no such i, k, σ, σ', h exist to satisfy (1-3). Because the input ℓ induces a loop, we know that there is an infinite trace:

$$
\langle u_1, \sigma_1 \rangle \to \underbrace{\langle u_2, \sigma_2 \rangle}_{t_1} \to \langle u_3, \sigma_3 \rangle \to \langle u_4, \sigma_4 \rangle \to \underbrace{\langle u_5, \sigma_5 \rangle}_{t_2} \to \langle u_6, \sigma_6 \rangle \to \ldots
$$

Because the set of headers $\mathcal{H}$ comprising the hops in $\mathcal{H}^*$ is itself finite and because there is a permanent loop, there must be an infinite number of time steps $t_1, t_2, t_3, \ldots$ where the stack never goes below the size at time t_i in the future – i.e., $\forall j, \ j \geq t_i \Rightarrow |\sigma_{t_i}| \leq |\sigma_j|$. If there were no such infinite sequence, then there could not be a permanent loop since at some point t^*, the stack would have to continue to shrink forever ($\forall j_1, \ j_1 \geq t^* \Rightarrow \exists j_2, \ j_2 > j_1 \wedge |\sigma_{j_1}| < |\sigma_{j_2}|$) and would eventually become empty since stacks are finite. This would contradict the fact that there is a permanent loop since the packet would eventually be dropped when the stack becomes ε.

From the sequence of $t_1, t_2, t_3, \ldots$ and the finiteness of the topology, eventually there must eventually be a subset of t_i which we will call $t_{m_1}, t_{m_2}, t_{m_3} \ldots$ that repeat at the same node with the same top of stack:

$$\langle u_1, \sigma_1 \rangle \rightarrow \underbrace{\langle u_2, \sigma_2 \rangle}_{t_1} \rightarrow \langle u_3, \sigma_3 \rangle \rightarrow \langle u_4, \sigma_4 \rangle \rightarrow \underbrace{\langle u_5, \sigma_5 \rangle}_{t_2} \rightarrow \langle u_6, \sigma_6 \rangle \rightarrow \ldots \rightarrow \underbrace{\langle u_i, \sigma_i \rangle}_{t_{m_1}} \rightarrow \ldots \rightarrow \underbrace{\langle u_k, \sigma_k \rangle}_{t_{m_2}} \rightarrow \ldots$$

where $u_{t_{m_1}} = u_{t_{m_2}}$, and $\text{top}(\sigma_{t_{m_1}}) = \text{top}(\sigma_{t_{m_2}})$ and so on for all t_{m_i}. Because we know that at time t_{m_1} the stack $\sigma_{t_{m_1}}$ never again goes below this size, if $\sigma_{t_{m_1}} = \sigma \cdot h$, then every stack in the trace from this time on must start with σ. The earliest two times t_{m_1} and t_{m_2} capture exactly i, k in the theorem, and $\sigma_{t_{m_1}}$ captures $\sigma \cdot h$ (condition 1). The trace retains the prefix σ after time t_{m_1} (conditions 2, 3). And the nodes and top of stacks are the same at each time t_{m_i} being h (condition 2). $\qquad\square$

Enabling In-situ Programmability in Network Data Plane:
From Architecture to Language

Abstract

In-situ programmability refers to the capability for network devices to update data plane functions and protocol processing logic at runtime without interrupting the services, driven by dynamic and interactive network operations towards autonomous networks. The existing programmable switch architecture (e.g., PISA) and programming language (e.g., P4) were designed for monolithic and static implementation, which requires a complete programming and deployment cycle for functional update, incurring long delay and service interruption. Addressing the fundamental reasons for such inflexibility, we design a new In-situ Programmable Switch Architecture (IPSA) and the corresponding design flow using rP4, a P4 language extension, as a fix. The compiler contains algorithms to support efficient resource mapping for both base design and incremental updates. To manifest the in-situ programming feasibility, we demonstrate several practical use cases on both a software switch, `ipbm`, and an FPGA-based prototype. Our experiments and analysis show that IPSA incurs moderate hardware cost which can be justified by its benefits and compensated by newer chip technologies. The in-situ programmability enabled by IPSA and rP4 advances the state of the art of programmable networks and opens a promising new design space.

1 Introduction

High-performance networking devices are usually built with hardware centered on a forwarding chipset [1–5]. The diverse network types require varied feature sets; new protocols (e.g., SRv6 [6]) and functions (e.g., INT [7]) keep emerging; meanwhile, the demand for higher throughput never relents. It becomes increasingly uneconomical or even infeasible to integrate all needed features and functions in a single chip at design time. While the future networks are expected to evolve to be autonomous with the capability of self-provisioning, self-diagnosing, and self-healing, the network operations will become more dynamic and interactive, aggravating the performance and flexibility pressure on network data plane.

We argue that the network data plane requires the in-situ programmability, which refers to the capability for network devices to update data plane functions and protocol processing logic at runtime without interrupting the services. Specifically, it ensures that (1) the on-demand and incremental part can be patched into the existing system in service without full design recompiling and reloading, (2) unused functions can be removed to preserve resource and energy, and (3) the update process has near-zero impact on network services and incurs little delay, permitting realtime interactive control loops. The need for in-situ programmability is evidenced by the following non-exhaustive list of applications:

Network slicing. A network device can be programmed to support multi-tenancy using network slicing [8, 9]. Due to the resource limitation and the application dynamics, tenants with custom policy and processing logic may be added, removed, or updated at runtime. Modifications for any tenant cannot affect the other tenants.

Network telemetry and measurement. Dynamic visibility is particularly useful to support closed control loops in autonomous networks based on realtime network conditions. However, such functions are either hard to foresee at design time or too expensive to keep permanent (e.g., sketch [10]), so it is better to make them on-demand at runtime. For example, the sketch size can be changed to get better traffic visibility as network pattern changes (e.g., DREAM [11] and SCREAM [12]); iterative debugging and query installation can be supported (e.g., Marple [13] and Path Query [14]); flows specification and associated actions can be refined and updated (e.g., Sonata [15] and ProgME [16]).

Trial on new protocols/algorithms. It was difficult to conduct live trials for new protocols/algorithms in production networks, in fear of disturbing or even disrupting network operation and incurring irrevocable damages. On the other hand, there is no better way to understand their impact and gain confidence. The dilemma can be dissolved by enabling inserting new protocols/algorithms to in-service network devices with a reliable failback procedure. Even better, a proven update can be made permanent without a network overhaul.

In-network Computing. Network devices can integrate a partial function for applications such as caching [17], aggregation [18], and coordination [19], to boost their performance and reduce system cost. Such a function can be resource-consuming but not always needed, and new functions may emerge, so it is better to make them pluggable at runtime.

Memory refactoring and repurposing. As the scarcest resource in a switch, the on-chip memory is shared by lookup tables, data cache, and packet buffers. The change of traffic pattern and network scale may raise new network optimization requirements or demand new functions, making it necessary to enlarge or shrink a table's width or depth, provision new tables, or change a search key.

State preserving for stateful functions. Conventional device updates can be destructive to the states of stateful functions stored in registers and memory tables, which need to be rebuilt from scratch or refreshed from the control plane. The detriments can be avoided if the states are preserved through hitless incremental updates.

Network data plane programmability has come a long way. The reconfigurable chips (e.g., FPGA and Network Processor) were the earlier attempts to make network devices programmable. In recent years, data plane programmability was pushed to a new height by two new developments. The packet processing and forwarding architecture was abstracted as a generic match-action pipeline (i.e., RMT-based PISA [20,21]), enabling a new type of programmable ASIC conforming to the architecture [3]; further, a high-level domain-specific language P4 [22] was developed as the chief programming language for such an architecture, which helps to accelerate the development life cycle and support design reuse and cross-platform migration. The flexibility has triggered numerous innovations, such as *in-network computing* [17, 23, 24] and *programmable network visibility* [7, 10, 25].

However, such programmability still falls short of the requirements of the aforementioned applications. The fundamental issue is that such programmability is static and limited to design time. The packet processing pipeline, once compiled and installed, cannot be changed any more during the runtime. Any new function update, no matter how minor it is, requires modifying and recompiling the complete source code, swapping in the resulting monolithic "binary", and repopulating all the tables, which inevitably introduce delay and service interruption.

Several attempts have been made from different angles to achieve higher flexibility for data-plane programmability [9, 26–29]. However, none of them can realize the desired in-situ programmability in hardware. To this end, we reason a new chip architecture other than PISA is needed, as well as the corresponding programming model. Specifically, we make the following contributions:

• We develop a new In-situ Programmable Switch Architecture (IPSA) with four key components to provide enough flexibility for in-situ programming (Sec. 2).

• We design a P4 language extension, reconfigurable P4 (rP4) (Sec. 3.1), and develop the corresponding design flow and compilers for IPSA-based device programming (Sec. 3.2); we integrate in the rP4 compiler efficient algorithms to solve the resource mapping issues raised by IPSA and incremental updates (Sec. 3.3); we detail the non-disruptive update deployment procedure (Sec. 3.4).

• We implement an IPSA-complying software behavioral model, ipbm, used as a tool to verify the rP4 compiler and test applications, similar to the role of bmv2 to P4. We also implement an FPGA-based IPSA prototype and use it to demonstrate several use cases (Sec. 4). We open source the rP4 specification, compiler, and ipbm [30]. Through experiments and analysis, we confirm that IPSA/rP4 supports non-disruptive and low-latency in-service updates, and exhibit the hardware cost and potential trade-offs (Sec. 5).

After discussing the limitations, potentials, and future work (Sec. 6), we brief the related work (Sec. 7) and conclude the paper (Sec. 8)*.

2 In-situ Programmable Switch Architecture

2.1 Motivation

To make in-situ programmability possible, it is crucial to understand why the current programmable switch architecture and programming model are incapable. We summarize the main reasons as follows:

• The packet header parser and the corresponding processing logic are decoupled. The parsing states in the standalone front parser are entangled with different pipeline stages, and a function block cannot be made self-contained and independent. Hence, an update may need to modify multiple places in a program, which is cumbersome and error-prone. Moreover, without knowing the actual processing a packet undergoes, the front parser may parse fields that the pipeline never uses, wasting parsing cycles and header vector storage.

• The pipeline stages are hardwired into a chain, on which the actual packet processing pipeline is mapped in order, resulting in several unfavorable consequences: (1) the maximum number of ingress and egress stages is fixed, limiting the design flexibility; (2) unused stages are kept in the chain, potentially increasing latency and power consumption; (3) even if each physical stage can be programmed individually, an update (e.g., inserting a stage into the pipeline) requires to reprogram all the affected stages (e.g., pushing all stages back to make room), which could be time-consuming.

• The memories for lookup tables are prorated over physical stages, implying that (1) the processing logic migration results in the associated table migration as well which increases the update delay, and (2) if the table size required exceeds

---

*This paper extends our workshop paper [31] with updates including the introduction of virtual pipeline, detailed resource mapping algorithms, non-disruptive deployment procedure, and more evaluation results.

what is provisioned in a single stage, more stages need to be combined, which reduces the effective pipeline stages.

• A pipeline-oriented P4 program can only be compiled into a monolithic "binary" file in which the individual functions are unextractable and the actual pipeline mapping is opaque to programmers, making incremental updates impossible. Some switches nominally support on-line reprogramming, suffering from considerable service interruption and packet loss.

To overcome the inflexibility of PISA and support in-situ programming, while retaining its match-action pipeline abstraction, we design a new switch architecture, IPSA, with four major architectural changes. The overview of IPSA is illustrated in Fig. 1.
Figure 1: Overview of IPSA.

2.2 Distributed On-demand Parsing

In-situ programming implies a modular design style in which functions are self-contained. IPSA eliminates the front parser. The complete parsing graph is split into sub-graphs and distributed just in time to each pipeline stage, ensuring the self-sufficiency of each pipeline stage and avoiding unnecessary parsing. The parsing cost is amortized over active pipeline stages, making the design more scalable.

A parsing sub-graph in each stage instructs the local parsing process. Instead of a Packet Header Vector (PHV), a window of packet header bytes plus some metadata pass through the pipeline. The parsing result at each stage is recorded as {*hdr_id, hdr_offset, hdr_length*}, which is also passed to subsequent stages to avoid unnecessary re-parsing. A field in a header can be obtained using the configured {*fld_offset, fld_length*}. The design eliminates the need for deparsing at the end of a pipeline. The offset management module is responsible for adjusting the parsed header offsets in the case of header length change (e.g., MPLS label push and pop).

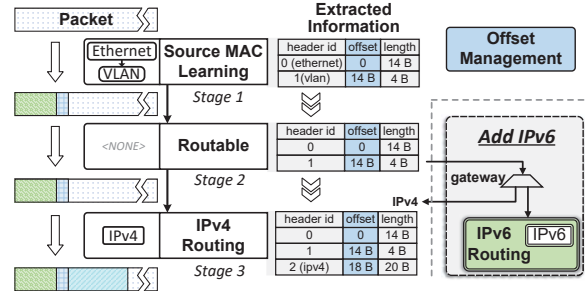
In the example shown in Fig. 2, the complete parser for `Ethernet`, `VLAN`, and `IPv4` is distributed into the first and the third stages. To add IPv6 support later, we can write a standalone function module which takes care of its own parsing need. There is no need to modify the other modules except for configuring the branching gateway or flow actions in the new module's direct predecessors (see Fig. 2). The distribution of


Figure 2: Distributed on-demand parsing.

a parser for a specific design is determined by the compiler. The algorithm is provided in Sec. 3.3.

2.3 Templated Stage Processor

Due to the distributed parsing, each pipeline stage processor now contains three sub-modules: a parser, a matcher, and an executor. The matcher and executor conduct the similar match-action function as in PISA.

IPSA pipeline stages are just loosely coupled, and each stage is individually programmable. By separating primitive and parameter [27, 29], each processor appears to be a parameterized container in which three abstractions are applied: (1) header fields are abstracted as *offset* and *length*; (2) flow tables are abstracted as *type*, *size*, and *key*; (3) actions are abstracted as an ordered set of primitives and their parameters. Programming a Templated Stage Processor (TSP) simply means downloading the template configurations, such as header field indicator, match type, table specification, and action, to it. TSP is a key mechanism to enable local and independent updates, allowing us to modify the function of each TSP at runtime.

2.4 Virtual Pipeline

In IPSA, the TSP interconnections are not hardwired. Instead, a reconfigurable non-blocking interconnection network (e.g., crossbar) is used. When including the packet I/O and Traffic Manager (TM) in the interconnection, we can dynamically generate arbitrary virtual pipelines in which a TSP can be allocated to any stage in either ingress or egress, regardless of its physical location, or excluded from the pipeline if unused, which can be kept in low power state to reduce heat. As long as the total number of required pipeline stages is no more than the number of TSPs, the design can be supported.
Figure 3: A virtual pipeline example.

We make a trade-off between the latency and scalability by choosing either a crossbar or a multi-stage network for TSP interconnection. Virtual pipeline maximizes the flexibility in constructing a pipeline and simplifies runtime updates. When needing to insert or remove a TSP in the pipeline, one just needs to reconfigure the interconnection network. In the example shown in Fig. 3, TSP1-TSP4-TSP2 forms the ingress pipeline, TSP5 forms the egress pipeline, and TSP3 remains in idle. The algorithm for logical stage to TSP mapping, as part of the compiler, is provided in Sec. 3.3.

2.5 Disaggregated Memory Pool

IPSA disaggregates the memory from TSPs to a shared memory pool as in dRMT [32]. A crossbar switch fabric is statically configured for each design to provide interconnection between TSPs and memory blocks. Updates on either TSPs or tables may require a reconfiguration of the crossbar. To cope with the scalability, different optimizations [32] can be used as a trade-off between flexibility and resource consumption. Specifically, we partition the TSPs and memory blocks into multiple clusters and each cluster has a crossbar for TSP-memory interconnection. In each cluster we can also apply the segment optimization [32] to further improve the scalability. Note that the clustering optimization is inapplicable to dRMT because its Run-to-Completion (RTC) processors require table replication in each cluster. The one-to-one mapping between processor and table in our architecture frees it of processor synchronization and crossbar scheduling.

Each SRAM table is mapped to some memory blocks which are not necessarily adjacent. The TCAM table virtualization technique is similar to that in RMT [20, 32]. The compiler determines memory allocation for the initial design and incremental updates. Once deployed, network operators use the APIs provided by the compiler to access the logical tables at runtime. If a logical stage is deleted, the memory blocks for its associated table are recycled.

Disaggregated memory pool allows multiple TSPs to read or write the same logical table, enabling single-pass *stateful* data-plane functions which was difficult or even impossible to realize in PISA.

3 rP4 Language and Compiler

IPSA makes local function updates possible while keeping the other incumbent functions and states intact. While IPSA paves the hardware foundation for in-situ programmability, software tools adapting to it are needed. The language should be a high-level one to ease programming, yet a paradigm shift, i.e., using a modular and stage-oriented design to replace the monolithic and pipeline-oriented design, is required. Meanwhile, we should try the best to take advantage of existing assets (e.g., P4) and avoid reinventing the wheel.

3.1 rP4 Language Overview

In IPSA, the packet processing pipeline consists of stages with each performing some parse-match-action triad. The incremental parts are inserted into the pipeline as new stages. To this end, we design a P4 language extension, rP4, dedicated to programming IPSA-based devices. The reason is multifold: P4 is familiar and supported by a mature community; we can reuse most of the existing language features; potentially we can mix rP4 code to P4 program for co-design optimization. In rP4, each *function* contains one or more *stages*, and each stage includes a *parser*, a *matcher*, and an *executor* module. The table information can be extracted from the matcher. The grammar of rP4 is given in Appendix A.

3.2 rP4 Design Flow

Illustrated in Fig. 4, the rP4 design flow comprises two parts: the base design and incremental updates upon it.
Figure 4: The complete rP4 design flow.

3.2.1 Flow for Base Design

We use P4 instead of rP4 for the original base design because P4 code is easier to write and many proven designs in P4 exist. Moreover, a design in P4 can be mapped into both PISA and IPSA-based devices, albeit the former does not support runtime incremental updates.

The rP4 front-end compiler, `rp4fc`, transforms P4 code into rP4 code. Specifically, `rp4fc` takes the HLIR, the target-independent output of `p4c`, as input, and outputs the semantically equivalent rP4 code. `rp4fc` also produces the APIs for network operators to access the tables at runtime.

To generate the final TSP and table mapping, we develop an rP4 back-end compiler, `rp4bc`. It takes rP4 code as input, analyzes the dependency of different logical stages, optimizes the predicates to merge some independent stages into a single TSP, allocates tables, and computes the best stage mapping layout. The output of `rp4bc` is the TSP templates in JSON format, which are used to configure the data-plane devices.

3.2.2 Flow for Incremental Updates

In-situ programming uses `rp4bc` as well. With the help of the rP4 base design, users gain insight into the pipeline and decide

the location for updates. To insert a new function, we write the rP4 code snippet. We then feed the commands, which stipulate the operation and location, plus the rP4 code to `rp4bc`. `rp4bc` generates two outputs: the first output is the updated base design as the reference for future updates, and the second output is the new TSP templates and switch configuration. We use another command and an rP4 function name as parameters for function deletion. Similarly, the base design is updated and new data-plane templates and configurations are generated.

3.3 Algorithms in rP4 Compiler

The rP4 compiler needs to solve two problems: the parser distribution and the mapping from logical stage to physical processor.

3.3.1 Parser Distribution and Mapping

A parser is essentially a Finite State Machine (FSM) which can be represented as a Header Parsing Graph (HPG). Fig. 5(a) shows an example of HPG in which each node represents a header. The packet processing flow is partitioned into logical stages to form a Processing Flow Graph (PFG). Each node in PFG represents a logical stage which contains a set of headers needed either for table lookup or packet processing. A PFG example is shown in Fig. 5(c).

The parser distribution problem is to determine which header(s), if available, should be parsed at each logical stage while obeying the just-in-time principle. Obviously, at each logical stage, a needed header, as well as all its predecessors in HPG, should be parsed on each path in PFG leading to the current stage. The parser distribution algorithm determines the mapping of a minimum sub-graph of HPG to each logical stage in PFG. We have two cases: the mapping for the base design and for incremental updates.

(a) HPG.

(b) Reverse mapping from header to logical stages.

(c) PFG. Below each node is the resulting distributed parser states.
Figure 5: Mapping of distributed just-in-time parser.

Base Mapping. We construct a distributed parser for each logical stage s in the topological order of PFG. At s, for each reverse path p tracing back to the root of PFG, if a needed header i in s has been parsed, we extract a sub-graph containing i and all its predecessors in HPG which have not been parsed on p. At last, the sub-graphs for all the reverse paths are merged to generate the distributed parser for s. Fig. 5(c) shows the final mapping result for each stage if the PFG nodes is processed in the order of a-b-c-d-e-f-g-h.

To fit the internal pipeline structure of a TSP, the maximum parsing depth of a distributed parser is limited to a pre-defined value h. In case the depth H of a resulting parser exceeds h, the original logical stage is split into $\lceil H/h \rceil$ sub-stages and the parser is divided into $\lceil H/h \rceil$ sections to fit in them. Only the last sub logical stage contains the original matcher and executor. Although mapping to different TSPs, these sub-stages jointly serve as the original logical stage.

It is trivial to prove that the algorithm can guarantee the just-in-time parsing. The complexity of the algorithm is $O(V_H + E_H + V_P + E_P + V_d)$, where V_H, E_H, V_P, E_P, and V_d represent the number of vertices and edges in HPG, the number of vertices and edges in PFG, and the total number of needed headers by the logical nodes in PFG, respectively.

Incremental Update Mapping. On the basis of HPG and PFG, we can avoid rebuilding the parser mapping each time an incremental update occurs, to reduce the compiling time and update cost. However, both HPG and PFG may change as a result of the changes on protocol header, logical stage, and stage transition. To solve the problem, we establish a reverse mapping from HPG nodes to PFG nodes. Each HPG node i is associated with a set of logical stages in which the header i is parsed. The result for our example is shown in Fig. 5(b).

In PFG, the parser change on s does not influence its predecessors. If a removed header i in s may cause another header j in some predecessor stage s' to become redundant, it means j is not needed in s' in the first place. The just-in-time parsing makes this case impossible. If a new header i is added to s, s is solely responsible for parsing all i's predecessors in HPG that are not parsed yet on all the paths leading to s in PFG. Therefore, we have the following procedure for two cases of HPG change. (1) A header i insertion or deletion in s: find all the direct successors of i in HPG and get their corresponding logical stages from the reverse mapping. Update the parsers in s and these logical stages as well as their successors in topological order of PFG. (2) A topology change in HPG: get the corresponding logical stages from the reverse mapping for all the influenced headers and update the parsers in these stages and their successors in the topological order of PFG. During the update, if all the direct predecessors of s' do not change their parsers, then s' does not need to change its parser either, so the update process can stop earlier.

Similarly, for a change in PFG, we have the following two cases. (1) A logical stage s insertion or deletion: update the parsers in all s's successors in topological order of PFG. (2)

A topology change in PFG: find all the influenced stages and their successors, and update the parsers in these stages in topological order of PFG. Although the time complexity is the same as the base mapping, in practice the incremental update mapping is much faster.

3.3.2 Logical-to-physical Topology Mapping

Unlike the logical-to-physical pipeline mapping problem in PISA [20, 33], the PFG-to-TSP mapping in IPSA faces different freedom and constraint due to virtual pipeline and disaggregated memory cluster. The high level goal is to minimize the number of required TSPs and maximize the potential to support incremental updates.

Assume there are m TSP clusters, $\mathbb{C} = (C_1, C_2, ..., C_m)$, and each cluster i has n TSPs $P_i = (p_{i,1}, p_{i,2}, ..., p_{i,n})$ sharing s SRAM blocks and t TCAM blocks.

Base Mapping. Let $P(v)$ denote the TSP to which the logical stage represented by node v in PFG is mapped and $V(p)$ denote the set of independent logical stages mapping to the TSP p. We model the mapping from PFG to TSP as an ILP problem with the following constraints and objectives:

Constraint 1: Successor Exclusion. Any two logical stages cannot be mapped to the same TSP if they are on the same path in PFG. That is,

$$P(v_i) \neq P(v_j), \ if \ v_i \succ v_j \ or \ v_j \succ v_i \qquad (1)$$

in which "$\succ$" denotes the successor relationship.

Constraint 2: Path Order. The active TSPs form a pipeline on which the logical stages on the same path in PFG must follow the pipeline order. That is,

$$\forall \ v_i, v_j \in V, \ if \ v_i \succ v_j \Rightarrow P(v_i) \succ P(v_j) \qquad (2)$$

Constraint 3: TSP Capacity. The number of parallel logical stages that can be mapped to a single TSP is limited to a predefined value, K, depending on the TSP resource. That is,

$$\forall \ p \in P, \ |V(p)| \leq K \qquad (3)$$

Constraint 4: Flow Table. The total number of memory blocks required by the logical stages mapped to the TSPs in a cluster should not exceed the available resource. That is,

$$\forall \ C_i, \ \sum_{1 \leq j \leq n} s(p_{i,j}) \leq s, \ \sum_{1 \leq j \leq n} t(p_{i,j}) \leq t \qquad (4)$$

in which $s(p)$ and $t(p)$ denote the number of SRAM and TCAM blocks required by the TSP p, respectively.

Objective 1: To save more TSPs for future updates, the number of active TSPs should be minimized by mapping independent logical stages to the same TSP. Let $a(p)$ be 1 if p is active and otherwise be 0. The objective is therefore,

$$\min \sum_{1 \leq i \leq m, 1 \leq j \leq n} a(p_{i,j}) \qquad (5)$$

Objective 2: The initial mapping should satisfy the processor and memory requirements with as few clusters as possible, so as to concentrate the unused resources in some clusters to make logical stage and table allocation for future updates easier. Approximately, the objective is expressed as,

$$\max \sum_{C_i \in \mathbb{C}} m_i^2 \sum_{1 \leq j \leq n} (\frac{K - u_{i,j}}{K})^3 \qquad (6)$$

in which m_i is the ratio of free memory blocks in cluster C_i, and $u_{i,j}$ is the number of used stage resources in $p_{i,j}$. The formula favors more free processors.

We use the open-source ILP solver YALMIP [34] to solve the problem. For the example in Fig. 6(a), the base mapping result is shown in Fig. 6(b), and the virtual pipeline is $(a) \rightarrow (c) \rightarrow (b,f) \rightarrow (d,e) \rightarrow (g) \rightarrow (h)$.

Incremental Update Mapping. To make incremental changes for each runtime update (e.g., insertion or deletion of a function), we use a *greedy mapping* algorithm other than ILP to obtain a local optimal solution, because ILP is not only slower but also possible to significantly change the mapping result which requires excessive stage and table migrations.

Greedy Mapping. We maintain a profile for each cluster to record its free SRAM blocks, TCAM blocks, and the usage of TSPs (Fig. 6(b)). The logical stage insertion performs the following steps: first, exclude the clusters without enough free memory blocks required by the new stage; second, check whether any processor in the remaining clusters can accommodate the new stage under the constraints (1), (2), and (3); third, in the feasible clusters, choose the one based on the objective (6). In Fig. 6(a), a new stage **i** which needs 2 SRAM blocks is inserted. $p_{3,2}$ is selected as the greedy mapping result shown in Fig. 6(c).

3.4 Non-disruptive Update Deployment

After update compiling, the update deployment handles the device configuration. Since an update may need to insert or delete multiple logical stages on multiple TSPs, the device configuration involves multiple tasks: initialize the TSP templates and logical tables, reconfigure the TSP-memory crossbar and the virtual pipeline, and modify the transitional logic of the affected predecessor stages. The update deployment needs to meet three requirements. (1) *Consistency*: any packet in pipeline must be processed either before or after an update takes effect; (2) *Non-disruption*: the deployment process should not cause service interruption or packet drop; (3) *Low latency*: the time taken should be minimized.

The deployment procedure we use is named Big Bubble Update (BBU). BBU can make an update take effect within a fixed time window at the cost of a small buffer in front of the processing pipeline. As illustrated in Fig. 7, any update can be decomposed into a set of three basic operations:

MOD. When needing to modify logical stages in TSP2 (and any other TSPs after TSP2), TSP1 is first stopped from

(a) PFG with SRAM (S)/TCAM (T) requirements for each stage. 'd' and 'w' denote the depth and width of a memory block, respectively.

(b) Base mapping result. There are 4 clusters with each having 2 TSPs, 16 SRAM blocks, and 4 TCAM blocks.

(c) The result mapping after inserting stage **i**.
Figure 6: The base and runtime update mapping from logical stages to physical processors.

moving packets to TSP2 to drain TSP2 in time T. After that, d more clock cycles are used to configure TSP2. Then the packet flowing resumes. The other TSPs that need to be modified will take turn when the created bubble arrives.

DEL. The gateway in a TSP determines in which following TSP and logical stage a packet should be processed. When needing to deleting a logical stage s in TSP3, the preceding TSPs need to modify their gateways if their direct target is s.

INS. It is much easier to insert a new TSP with new logical stages into the pipeline. There is no need to halt any part of the pipeline during the d clock cycles used for new TSP configuration. Both DEL and INS just need one clock cycle to reconfigure the pipeline interconnection as the last step.
Figure 7: BBU example. When TSP1 is halted, new arrival packets are accumulated in the front buffer.

BBU guarantees the update consistency (i.e., any packet cannot be partially processed by an updated function). A MOD update takes effect after at most $(T+d)$ clock cycles, and DEL and INS updates take much shorter time, meaning that an update can be performed as soon as there is enough space for $(T+d)$ packets in the front buffer. A complex example in Fig. 8 shows that multiple updates can be achieved with one big bubble as well.

4 Implementation and Use Case Demo

To verify the architecture and programming flow, we build both software and hardware IPSA prototypes, on which several use cases are demonstrated.

4.1 IPSA Prototypes

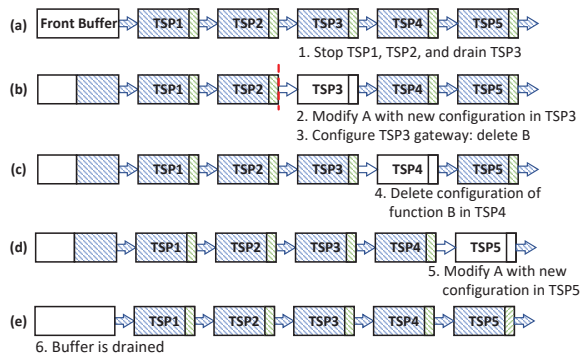
Software Switch: We implement a behavioral model, `ipbm`, on Ubuntu 20.04 LTS as a reference software switch con-


Figure 8: Function A resides in TSP3 and TSP5; Function B resides in TSP4. To modify A and delete B, the updates are performed in order when the target TSP is in the big bubble.

forming to IPSA. `ipbm` takes 8,361 lines of C++ code. `ipbm` consists of four modules: the Communication Module (CM) supports OS kernel bypass and direct packet I/O; the Pipeline Module (PM) simulates the TSPs; the Control Channel Module (CCM) communicates with the controller for runtime configuration; the Storage Module (SM) realizes the disaggregated memory pool.

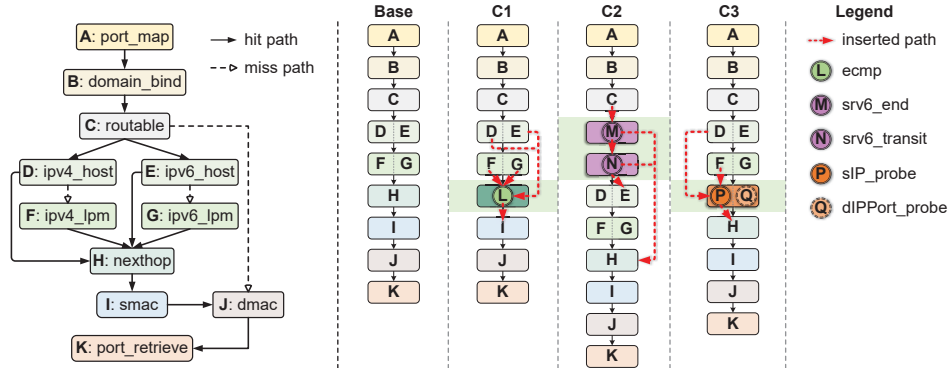
Hardware Switch: We build a hardware prototype on a Xilinx Alveo U280 accelerator card. The Xilinx 16nm Ultra-Scale+ FPGA contains 8GB of HBM2 memory with 460G/s bandwidth [35]. We implement both IPSA (2,366 lines of Scala code) and PISA (1,942 lines). Each prototype contains 12 physical processors (K=2). The TM is omitted for simplicity. Each IPSA TSP supports a 192-byte packet window, 64-byte metadata, and a 4-level pipelined parser. The TSPs are partitioned into 3 clusters, each with 64 256×64b memory blocks. The maximum bus-width for memory access is limited to 256-bit (i.e., four memory ports) for both prototypes. Each executor contains four primitives which are sufficient to our use cases. We implement both memory blocks and virtual pipeline interconnections with a 12×12 full crossbar. The PISA prototype realizes a 256-byte PHV which comprises 32x 8-bit, 48x 16-bit, and 32x 32-bit containers. Each


Figure 9: The packet processing flow and TSP pipeline mapping for the use cases.

processor in PISA can access 16 memory blocks.

Compiler and Controller: rp4c is implemented with 3,772 lines of C++ code. The controller is used for runtime configuration and in-situ programming. We implement a simple command-line interface in C++, allowing users to load or offload on-demand protocols and functions at runtime.

4.2 Base Design Compiling Results

We compile several open source P4 projects [17, 36–39] for ipbm and bmv2. Table. 1 shows the number of logical stages (*LS*) and the number of logical pipeline levels (*LPL*) on ipbm. bmv2 produces the same LPL results. The table also shows the average depth of the distributed parsers (*ADP*) and the percentage of the distributed parsers whose depth is under 5 (*U5*), confirming 4 is a good trade-off for the supported parser depth in a TSP.

	LS	*LPL*	*ADP*	*U5* (%)
switch.p4 [36]	130	31	0.28	100
DC.p4 [37]	38	19	0.45	97.37
ONTAS [38]	22	8	0.36	100
P4SRv6 [39]	17	5	0.53	100
NetCache [17]	96	14	0.21	100

Table 1: Design compiling results.

4.3 In-situ Programming Use Cases

To fit in our hardware prototype, the base design, as shown in Fig. 9, is extracted from switch.p4, which includes L2 switching with IP subnet-based VLAN and L3 forwarding based on IPv4/IPv6. The workflow is as follows: (1) get interface index via port mapping table (**A**), (2) bind the Bridge Domain (BD) and the Virtual Routing Forwarding (VRF) table (**B**), (3) determine L2 or L3 forwarding (**C**), (4) derive the egress interface index via BD and dMAC (**J**), (5) process IPv4/v6 header and get the next-hop (**D, E, F, G**), (6) update BD and dMAC via nexthop (**H**), (7) update sMAC via updated BD (**I**), (8) get the egress port via egress interface index (**K**). As shown in Fig. 9, the resulting PFG contains 11 logical stages

mapping to 9 TSPs. To showcase the in-situ programming capability, we select three representative applications which introduce new functions or protocols to the switch at runtime.

C1: Equal-Cost Multi-Path Routing (ECMP). While there are multiple network load balancing algorithms, we choose ECMP [40, 41] as an example to augment the base design. After the FIB lookup, the function chooses a forwarding link based on the next-hop and flow ID hashing. ECMP does not introduce new protocols, but two new tables and processing logic. The rP4 code for the ECMP function is shown in Fig. 10(a). ECMP applies for both IPv4 and IPv6. Since they are independent, only one physical stage is needed. The function also covers and therefore replaces the stage **H**. To insert the ECMP function into the original switch, we first compile the function code and the associate configuration script (Fig. 10(b)) into template parameters and required topology modifications, and then apply the configurations on the device. In this case, users need to link IPv4 forwarding and IPv6 forwarding with ecmp. The links from and to the original nexthop are removed through 'delete_link' command to eliminate the old function from the pipeline.

C2: IPv6 Segment Routing (SRv6). SRv6 [42] is an IPv6-based source routing protocol. It uses a new IPv6 extension header (i.e., SRH) to carry the forwarding path information [6, 43]. The SRv6 function has two sequential logical stages, srv6_end and srv6_transit, for SR end-point and transit-node processing, respectively. A packet first goes through the srv6_end stage. If the packet's SID matches the local SIDs of the switch, the end-point function is executed; otherwise, the transit-node function in the srv6_transit stage is executed, which could insert an SRH to the packet or simply forward the packet. In this case, the script for loading the function needs to link the new header into the original header list (Fig. 10(c)). Since the switch should still support pure L3 forwarding, the linkage between routable and ipvx is reserved. After rp4bc compiling and configuration downloading, the target is renewed with SRv6 support.

C3: Dynamic Flow Probe. To realize dynamic network measurement [11, 14], we insert an event-triggered probe at runtime and later the probe can be updated to change the object

```

2  ⋯ // omit stage topology change
3  link_header --pre IPv6 --next SRH --tag 43
4  link_header --pre SRH --next IPv6 --tag 41 // inner IPv6
5  link_header --pre SRH --next IPv4 --tag 4 // inner IPv4
```

(c) The script for loading SRv6 to `rp4bc`.

Figure 10: Code and script for runtime programming.

and trigger criteria. Specifically, we implement a heavy hitter detector based on SIP. Once a flow's traffic exceeds a threshold, the probe is triggered and user can apply pre-defined ACL or QoS rules to the flow. After a while, we switch the monitoring focus by using {DIP, DPORT} as the key, which requires policy update and table refactoring. The TSP mapping result is shown in Fig. 9. Since the probe works for IPv4, a link from IPv4 forwarding to the probe is added.

Due to space limitations, we omit the case for function/protocol removal, which is usually simpler than insertion.

5 Evaluation

First, we study the hardware cost for IPSA-based chips based on the FPGA prototype, theory analysis, and empirical evidence from previous study [20, 32]. Second, we conduct

experiments on the prototypes for IPSA and PISA using the aforementioned use cases to examine the performance such as forwarding throughput and latency, compiling time and configuration time for incremental updates, and power consumption. Due to the lack of real ASIC implementations, for some aspects, we can only gain the relative performance by comparing the IPSA and PISA prototypes.

5.1 Hardware Cost Analysis

We first analyze the cost of each key component and then provide an overall evaluation.

TSP. Table. 2 compares the FPGA resource (LUT and FF) consumption for a processor and shows that an IPSA TSP consumes 0.581% fewer LUTs and 0.847% more FFs than a PISA processor. The higher register consumption of IPSA is due to the need for template parameter storage.

Unit	LUT (%)		FF (%)	
	PISA	IPSA	PISA	IPSA
Parser	-	1.256%	-	0.684%
Matcher	4.131%	0.697%	0.295%	0.243%
Executor		1.597%		0.215%
Total	4.131%	3.550%	0.295%	1.142%

Table 2: Processor resource in FPGA prototypes.

Interconnection network for virtual pipeline. The number of TSPs determines the scale of the interconnection network. Different types of interconnection networks have different scalability and latency trade-offs. For N TSPs, we consider four types of non-blocking networks, i.e., Crossbar, Clos [44], Benes [45], and Batcher Banyan (BB) [46–48], which have characteristics in Table. 3.

Type	Cross-points	Latency (cycles)
Crossbar	N^2	1
Clos	$2Nc + N^2/c$	3
Benes	$4(N\log_2 N - N/2)$	$2\log_2 N - 1$
BB	$N\log_2^2 N$	$\log_2 N(1 + \log_2 N)/2$

Table 3: Cross-point comparison. c is the number of sub-switches in the second stage of Clos.

Clos is a good compromise between resource and latency. It is easy to derive that when $c = \sqrt{N/2}$, the minimum number of cross-points is achieved. For 32 TSPs, Clos can save 50% cross-points of Crossbar when $c = 4$. The network is composed of sixteen 4×4 crossbars and four 8×8 crossbars. Comparing to the internal latency of a TSP ($21 \sim 29$ clock cycles), the Clos network only adds three more cycles per stage. Based on the same assumption as in dRMT [32] (e.g., $200mm^2$ die size on 28nm technology for the entire chip), for an ASIC implementation, the die size of the Clos with 4Kb data bus width would be about $4.173mm^2$.

IPSA prototype implements a 12×12 crossbar for TSP interconnection. The data bus comprises 192-byte headers, 64-

byte metadata, 32-byte extracted information, 4-byte parsing states, and 6-bit configuration information (2,090 bits in total). The crossbar consumes 17.48% LUTs and 1.02% FFs of the FPGA, which account for 27.93% LUTs and 6.92% FFs consumed by all the TSPs, respectively.

Crossbar between TSPs and memory. Crossbar is used for memory access mainly due to the latency concern. dRMT uses a one-to-many segment crossbar to trade off the flexibility for scalability [32]. Equivalent to the configuration of RMT [20], it has 32 collections of memory blocks and 32 processors with each owning eight 80-bit memory access ports. Each matching key of a processor connects to a port in each memory collection, so the number of cross-points is $32 \times 8 \times 32 = 2^{13}$.

For IPSA, if we partition the 32 TSPs and memory collections into 8 clusters, and allow each TSP to connect to all ports in a memory collection, the number of cross-points would be $4 \times 8 \times (8 \times 4) \times 8 = 2^{13}$ as well. As a generalization, if we have M TSPs and M memory collections which are partitioned into m clusters, and each TSP connects to k memory ports, the number of cross-points is $M^2 k^2 / m$. When $M = 32$ and $k = 8$, by varying m, we get results in Table 4, in which the flexibility indicates the number of memory collections each TSP can access.

Type	m	Cross-points	Flexibility
IPSA	2	2^{15}	16
	4	2^{14}	8
	8	2^{13}	4
	16	2^{12}	2
dRMT	1	2^{13}	4

Table 4: Crossbar cross-point and flexibility comparison.

IPSA offers a wide design space for crossbar configuration. Higher memory flexibility (e.g., the capability to support large tables and the freedom for table mappings) can be gained with larger crossbar area. The crossbar in dRMT can be considered as a special case for IPSA. However, due to the lack of clustering, each of dRMT's processors needs to reach all the 32 memory collections, which increases the chip wiring latency and complexity. In contrast, to achieve the same number of cross-points, IPSA allows 8 clusters, and each TSP only needs to reach four memory collections.

Our IPSA prototype splits 12 processors into 3 clusters, resulting in 768 cross-points. The crossbar consumes 3.08% LUTs and 0.01% FFs of the FPGA, which account for 4.92% LUTs and 0.07% FFs of the IPSA prototype, respectively. Similarly, for an ASIC implementation with 32 TSPs, 8 clusters, eight 80-bit matching width, and return data containing eight 10-bit action pointers and 96-bit action data segments, the chip area of the crossbar is about $1.728mm^2$, similar to the result of dRMT.

Put everything together. The consumption of SRAM and TCAM is the same for IPSA and PISA, so the comparison

is omitted. Front parser and deparser are unique for PISA. The overall comparison of the two prototypes is shown in Table 5. The IPSA prototype consumes 12.09% more LUTs and 9.69% more FFs than the PISA prototype.

Protoype	PISA		IPSA	
Resource	LUT	FF	LUT	FF
Parsers/Deparsers	0.94%	1.54%	-	-
Processors	49.55%	3.52%	42.02%	13.72%
Crossbar	-	-	3.08%	0.01%
Inter-Network	-	-	17.48%	1.02%
Total	50.49%	5.06%	62.58%	14.75%

Table 5: FPGA resource for PISA and IPSA prototypes.

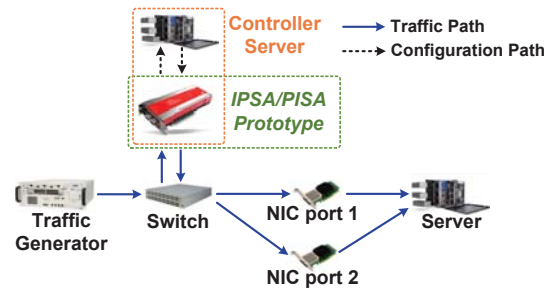
5.2 Experiment Settings


Figure 11: Testbed configuration.

Testbed. As shown in Fig. 11, the testbed is composed of the FPGA-based switch prototype, a server as the controller for switch configuration and control, a Spirent SPT-N4U-220 traffic generator [49] to generate test traffic, a server equipped with a Mellanox ConnectX-5 dual-port 100G NIC, and an Edgecore Wedge100BF-32X [50] switch to connect the devices. The FPGA has two 100Gbps QSFP28 Ethernet ports for data path traffic and one PCIe 4.0 interface supporting up to 16GT/s to the controller server. The Spirent SPT-N4U can generate up to 400Gbps packet trace with the accuracy of 10ns per frame. The traffic generator sends packets to the server through the FPGA. Because the FPGA has only one egress port, the Edgecore switch is used to split the traffic to the two NIC ports in order to demonstrate the ECMP function. The Edgecore switch is also programmed to timestamp the packets to and from the FPGA for latency measurement.

Packet Trace. Based on the use cases in Sec. 4.3, three types of packets shown in Table 6 are generated to test the prototypes. All the packets are 192-byte long with different numbers of padding bytes as payload. Each type of packet amounts to one third of the generated traffic.

5.3 Performance Evaluation

5.3.1 Switch Throughput and Latency

Throughput. With Vivado Design Suite [51], the synthesized clock frequency for IPSA is 110.45MHz and for PISA is

Header format	Header length (bytes)
`Ethernet-VLAN-IPv4-UDP`	46
`Ethernet-VLAN-IPv6-UDP`	66
`Ethernet-VLAN-IPv6-SRv6-UDP`	112

Table 6: Test packet types.

153.30MHz. The lower clock frequency for IPSA is due to the wiring complexity of the interconnection networks, which can be improved by the ASIC implementation. Benefited from the full pipelined design, theoretically, the IPSA and PISA prototypes can support a throughput of 169.65Gbps and 235.47Gbps, respectively. However, because the FPGA only has a 100Gbps interface, the peak throughput of the two prototypes is limited to 100Gbps.

Latency. We measure the forwarding pipeline latency based on the ingress and egress timestamps on packets. The results are shown in Fig. 12(a). The longer latency of the IPSA prototype is due to field and flow table profile fetching, match key assembly, and primitive loading. The gap can be mitigated and even reversed if the number of processors is large and the number of active processors is relatively small.

(a) Forwarding latency. (b) IPSA average pipeline latency.
Figure 12: Pipeline forwarding latency.

5.3.2 Incremental Update Deployment Delay

In addition to the rP4 design flow, we also implement the use cases in P4 design flow for comparison. Each time the updated source code is compiled by `p4c` and a PISA-based back-end compiler, and the FPGA prototype is loaded with the updated design.

The update process of PISA consists of two phases: compiling the updated code and reflashing the device. The latter causes pipeline interruption. In contrast, IPSA decomposes the second phase into two parts: configuration loading and update executing. Only the second part halts the pipeline. We use t_C, t_L and t_H to denote code compiling time, configuration loading time, and pipeline halting time, respectively. The update performance of PISA and IPSA is shown in Fig. 13. Similar comparison between `bmv2` [52] and `ipbm` is also included in terms of compiling time and halting time.

As shown in Fig. 13(a), since IPSA only compiles the updated code segment, it takes much shorter time than PISA. Fig. 13(b) shows that t_L of IPSA is much shorter than t_C. Fig. 13(c) exhibits that IPSA's pipeline halting time is only

(a) Compiling time t_C. (b) Loading time t_L of IPSA.

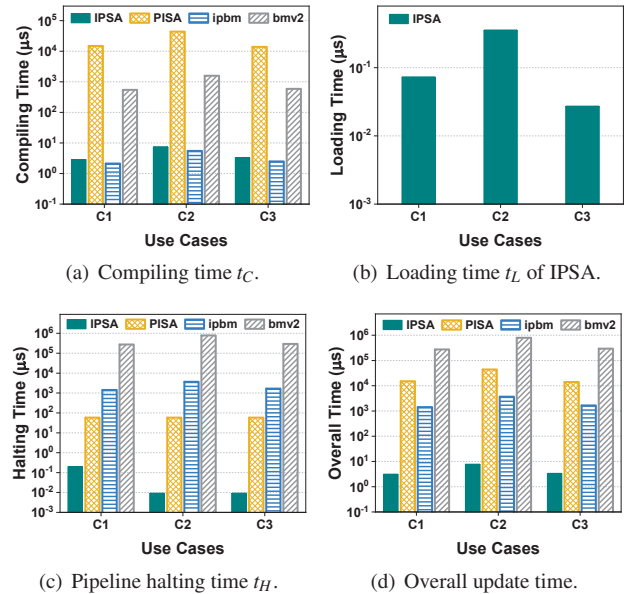
(c) Pipeline halting time t_H. (d) Overall update time.


Figure 13: Update performance.

0.34% of PISA's, allowing a small front buffer of 22 packets. Fig. 13(d) sums t_C, t_L, and t_H as the overall update time, showing that IPSA has much better update performance than PISA. The time comparisons between `ipbm` and `bmv2` in Fig. 13 lead to the same conclusion.

Fig. 12(b) shows the average pipeline latency before, during, and after each update in IPSA. C1, C2, and C3 are inserted and removed sequentially. While no packet drop is observed, the latency fluctuation is also small, revealing that the update deployment process of IPSA has negligible impact on packet forwarding. In contrast, any update in PISA needs to take the device offline and repopulate the tables, incurring longer latency and higher impact on packet forwarding.

5.3.3 Power Consumption

As a side benefit, the virtual pipeline in IPSA helps reduce the chip power consumption. We extend the number of processors to 32 and infer the power consumption of IPSA and PISA with different number of active processors using the Vivado Design Suite. We assume that the unused TSPs in IPSA are put in idle state while all the processors in PISA are active in the pipeline. As shown in Fig. 14, IPSA consumes less power when the number of active processors is smaller than 18. Since the extra interconnection networks in IPSA are both passively configured, we expect the ASIC implementation can achieve even better power efficiency.

6 Discussion and Future Work

Whenever possible we try to reuse the fruition of P4 and PISA in our design unless the issue is unique to our architecture.
Figure 14: Power consumption in terms of active processors.

Numerous design details omitted due to space limit in this paper are documented on the open source website.

In addition to the concurrency-based processor reduction [33], the resource mapping algorithm for updates can also be enhanced. To accommodate a new stage with memory requirement exceeding the free memory in any cluster, it is possible to relocate some existing stages to different clusters or split the new stage into multiple clusters.

The resource penalty for supporting IPSA can be offset by its unique properties and compensated by newer chip technologies: (1) A typical forwarding chip is usually built with multiple parallel pipelines. While PISA requires table replications in each pipeline, which reduces the effective memory resource, IPSA allows multiple pipelines to share a single copy of each table if multi-port memory blocks are provided. (2) In PISA, a big flow table requires combining multiple physical processors, reducing the effective pipeline stages. In IPSA, a logical stage can always map into a single TSP as long as its memory requirement can be satisfied by a cluster. (3) Since only active TSPs are kept in the pipeline in IPSA, the pipeline latency can be reduced, which offsets the extra latency introduced by the interconnection networks. (4) In IPSA, the statically configured interconnections for virtual pipeline and memory are more power-efficient than the dynamic switching network in dRMT. (5) The disaggregated architecture of IPSA also allows homogeneous components to be built on separate silicon chips and integrated with the 3D-IC technology [53–55], effectively expanding the available resource and reducing the memory access latency. It is conceivable to have a three layer chip architecture composed of processor, interconnection fabric, and memory. The detailed chip design and evaluation will be attended as future work.

The interconnection network allows the processors to be organized into a directed graph instead of a pipeline, which brings new design possibilities and challenges for parallel processing, deserving further research. On the other hand, while the full interconnection is resource intensive, we can explore the design space leaning to better resource efficiency but less flexibility as a trade-off (e.g., partial interconnection, blocking network, or bypassable pipeline stages).

It is also interesting to explore the possibility to automate the rP4 code generation by comparing the difference between the old and updated P4 programs. A GUI-based development environment would help visualize the pipeline and ease the programming process.

7 Related Work

dRMT [32] also decouples processors and memory, demonstrating the feasibility of resource pooling and crossbar-based interconnection; however, the RTC mode of processors excludes the possibility of incremental updates. POF [56] allows runtime table and function insertion into data-plane devices, but only applies on software-reprogrammable network processors rather than ASIC. IPSA adopts the similar approach as in POF to support distributed parsing. Some software switches (e.g., VPP [57]) support runtime updates as well but the techniques cannot be ported to hardware. daPIPE [58] allows users to integrate custom functions into the preexisting data-plane program, but still requires recompiling the integrated program. Mantis [59] supports predefined malleable values, fields, and tables whose semantics can be changed during runtime for reactive programming. While this is a step towards runtime behavior changing, the flexibility is limited and fine-grained, and the behavior must be predefined at design time. Hyper4 [9] virtualizes the data plane to adapt to various forwarding applications. Newton [29] supports a query template for dynamic telemetry, which is hard to extend. Some other works [8,27,60] virtualize network functions and match tables, but cannot support runtime data-plane programming. Limited to FPGA, Partial Reconfiguration (PR) [61] allows users to reconfigure pre-allocated regions at runtime. However, the performance and scalability issues make FPGA unsuitable for core switching chip, and the flexibility and deployment delay of PR still cannot match that of IPSA. Designed for smart NIC, PANIC [62] also uses a switching fabric for flexible compute unit interconnection, but a scheduler is needed to schedule the service chain for each packet.

8 Conclusion

IPSA and rP4 open a new design space for network programmability, enabling new applications in the era of autonomous networks. Our implementation and evaluation have demonstrated the feasibility and benefits of the new chip architecture and programming model. We open source the rP4 specification and compiler along with ipbm, with the expectation that our work can inspire a new breed of switch ASICs, engage the community to advance the language support, and help gestate novel in-situ programmable applications.

Abstract

Programming the network to add, remove, and modify functions has been a longstanding goal in our community. Unfortunately, in today's programmable networks, the velocity of change is restricted by a practical yet fundamental barrier: reprogramming network devices is an intrusive change, requiring management operations such as draining and rerouting traffic from the target node, re-imaging the data plane, and redirecting traffic back to its original route. This project investigates design techniques to make future networks *runtime programmable*. FlexCore enables partial reconfiguration of switch data planes at runtime with minimum resource overheads, without service disruption, while processing packets with consistency guarantees. It involves design considerations in switch architectures, partial reconfiguration primitives, reconfiguration algorithms, as well as consistency guarantees. Our evaluation results demonstrate the feasibility and benefits of runtime programmable switches.

1 Introduction

Programming the network to add, remove, and modify functions has been a longstanding goal in the networking community. Programmable switches [3, 8] represent the latest step toward this vision. Using high-level languages like P4 [3], network operators can customize packet processing behaviors at the switch program level. To change network processing, operators can deploy a different P4 program to the data plane, without the need for hardware changes or device upgrades. Programmable switches have enabled a host of new network applications in telemetry [15, 27, 35], measurement [40], security [39], and application offloading [18, 19].

Unfortunately, in today's programmable networks, the velocity of change is restricted by a practical yet fundamental barrier: switch functions are only programmable at compile-time, but they effectively become fixed functions at runtime. The switch program cannot be easily modified at runtime without reflashing the data plane hardware and carefully managing network-wide changes. To reprogram a network switch, operators need to first drain and reroute traffic from the target, install the new program image, and then redirect traffic back to its route. The error-prone nature of network maintenance procedures, the amount of manual coordination required, and the need to satisfy stringent SLAs pose severe constraints

on runtime program changes. To the extent that functions can be "hard-coded" in the device, they can be invoked for runtime response [41]. However, new functions that haven't been accounted for, or functions that cannot fit into the switch resources, are difficult to deploy at runtime. This stands in stark contrast to software data planes on host servers, where changes are easily accommodated and functions go through frequent upgrades [12]. The *ultimate* vision of programmable networks that seamlessly incorporates function changes *at any time* (e.g., based on traffic workloads or multi-tenancy requirements) still remains an elusive goal.

In this project, we pave the way toward *runtime programmable switches* by investigating the necessary building blocks and proposing concrete designs for each of them. FlexCore enables switch functions to be *continuously* programmable throughout the lifetime of the network. It develops a new set of control plane API to modify P4 program elements—match/action tables, control flow branches, and parsing graphs—while the switch data plane serves live traffic. These operations precisely instrument the switch program using *partial reconfiguration* primitives without affecting the rest of the data plane. This new modality of network programmability introduces an array of applications:

- Just-in-time network optimizations: When an optimization (e.g., network-accelerated multicast) is needed, it can be added just-in-time to serve the traffic workloads, and removed soon afterwards to keep the network lean.

- Real-time attack mitigation: If network attacks (e.g., DDoS, data exfiltration) are detected, we can inject mitigation modules exactly where needed; new attack patterns would trigger removal of expired modules and the insertion of new program components.

- Scenario-specific network extensions: A tenant can inject switch program extensions to the network. VM migration will carve out and graft the relevant program components to a different location of the network.

Also, telemetry applications do not have to commit to a fixed set of queries [27]; new network protocols can be added and removed dynamically; load-aware routing algorithms can be injected when needed [17]; different versions of switch programs can be deployed for canarying [42]. In fact, many (if not all) of today's programmable network applications will have more powerful, runtime programmable equivalents.

Achieving this goal requires a range of research challenges to be addressed: switch architecture designs that make runtime programmability natural, partial reconfiguration primitives for modifying live switch programs, atomicity and consistency guarantees on runtime changes, and algorithms for effectively computing reconfiguration plans. FlexCore makes contributions in all these dimensions.

Switch architecture. We base our FlexCore design upon a variant of disaggregated RMT (dRMT) [11]. dRMT separates switch memory from compute, and our architecture introduces another twist in its *partial* disaggregation design, where a small compute-local memory holds a indirection data structure that we call a *program description table* (PDT). This table contains metadata about the program control flow and is our target for reconfiguration. Decoupling program logic from its physical realization separates concerns: physical resources can be allocated and deallocated in scratch areas before program elements are modified for the changes to be visible.

Partial reconfiguration primitives. We develop a set of new primitives for adding, removing, and modifying program elements—this includes match/action tables, control flow branches and parser states. Unlike today's control plane API, which manipulates switch memory (e.g., adding/removing entries), the new API reconfigures switch compute.

Consistency guarantees. We propose three consistency guarantees for runtime reconfiguration: program consistency, element consistency, and execution consistency, with increasingly relaxed guarantees. These guarantees constrain the kind of "intermediate programs" that packets are allowed to encounter during partial reconfiguration. Program consistency states that all program modifications must take effect simultaneously. Element consistency is weaker, and states that modifications can be made visible in an element-by-element basis (e.g., one table at a reconfiguration step). Execution consistency is the weakest, but it still guarantees useful properties: packets never traverse execution paths that mix old and new program elements. In all cases, reconfigurations are atomic and do not disrupt data plane forwarding.

Algorithms. We develop algorithms for computing reconfiguration plans for different levels of guarantees.

Evaluation. We implement our design on a 12.8 Tbps merchant silicon (Nvidia Spectrum-2 SN3000 series), as well as a software simulator based upon bmv2. We evaluate the scalability of the reconfiguration algorithms and demonstrate a set of use cases in hardware and software platforms, showing that FlexCore enables a truly adaptive network core.

2 A Case for Runtime Programmability

The quest for network programmability has been an important undertaking in the community. Network switches used to be blackboxes, with opacity at both control and data planes. OpenFlow SDN opened up the control plane for programmatical control, and as of late, programmable data planes enable flexible packet processing pipelines without hardware upgrade. Operators can customize the data plane by removing unnecessary switch functions or adding new ones at the program level. P4 switch programs are compiled into a binary image, which is flashed to data plane hardware for deployment. Researchers have seized this opportunity to systematically rearchitect network telemetry [15, 27, 35], measurement [40], security [39], and application offloading [19].

However, today's programmable data planes have a notable limitation—they cannot be reprogrammed at runtime. If an operator can anticipate all required functions at compile time, and if these functions can fit into the switch resource constraints, then they can be combined and deployed together in the switch. But once deployed, the switch is committed to the hardcoded behaviors as specified at compile time, until the next program reflash. At runtime, only 'micro' changes are permitted, such as modifying flow table entries or register values from the control plane. This affords some flexibility [41]; however, as macro-level program logic changes are hard to make, accommodating requirements that truly arise 'on-demand' (e.g., security incidents) remain an elusive goal. Also, since switches have constrained resources, even if we had an 'oracle' planner that anticipates all needed functions, they may not fit into the switch together at compile time.

To remedy this problem, we need runtime programmable switches. This not only enables new use cases as motivated above, but also calls for a rethink as to how networks can be specialized. The operator can, at any point in time, aggressively optimize the network data plane to only retain a minimal amount of processing logic. This reduces switch resource footprints, improves network energy efficiency, and also keeps network latency at a minimum. If extra functionality is required, the program elements can be injected precisely where and when they are needed. If a functionality is no longer in use, it can be removed to ensure that the data plane stays at its leanest. Viewed from the lens of the classic 'end-to-end' arguments [31], in-network processing no longer incurs a common overhead to all applications.

3 The FlexCore Switch Architecture

Our switch architecture adopts a disaggregated RMT model [11], where compute resources (i.e., match/action processors) are split from memory (i.e., SRAM/TCAM), and they are interconnected via a crossbar. Each MA processor holds a copy of the P4 program, and processes packets in a run-to-completion manner.

In the RMT architecture [8], each stage contains a slice of compute and memory resources that cannot be reassigned to other stages. This tight coupling makes runtime reconfigurations challenging. For instance, inserting an MA table to a stage may require device-wide table shuffling and reallocation to make space. Removing an MA table from a stage will leave 'holes'—fragmented resources that cannot be easily reused by other program elements. These operations can be intrusive.

A disaggregated architecture, on the other hand, breaks
Figure 1: The FlexCore switch architecture. Highlighted in bold+italic are the customizations to dRMT [11].

resource allocation boundaries and enables reconfigurations to be performed locally—i.e., it enables *partial reconfiguration*. If a reconfiguration releases a table, the deallocated resources can be dedicated to *any* other program elements irrespective of their 'locations'. New tables can be inserted to any part of the program without having to change existing resource allocation decisions. Similar properties hold for resources that implement control flow branches and parsing graphs.

dRMT customizations. Our silicon also implements several customizations for performance, flexibility, and usability. Figure 1 shows the high-level architecture.

(i) Sharded resource allocation. In the dRMT architecture, an MA table is allocated in one specific SRAM/TCAM bank. Simultaneous accesses to the same table (or different tables in the same memory bank) from different processors creates contention at the crossbar. In FlexCore, all tables are *t*-way sharded, where *t* is the number of memory banks. When inserting a table entry, FlexCore first computes a hash *h* from the match key as the shard ID, and then allocates the entry in the *h*-th SRAM/TCAM bank. When performing a match, the same hash function is computed to retrieve the shard ID. This allows FlexCore to sustain linerate without complex mechanisms to detect and avoid access contention. The crossbar is always load-balanced and has uniform access patterns.

(ii) Hybrid programmability. Our switch exports a set of fixed-function ASIC modules as common building blocks (e.g., L2 bridging, L3 routing). These functions can be called by or bypassed from the P4-programmable logic. The fixed blocks are more resource- and energy-efficient, as their implementations are heavily-optimized, hardwired ASIC. By providing these building blocks, P4 programmers don't need to redevelop them from scratch. Moreover, they also represent a minimum "baseline" program that, if necessary, traffic can always fallback on during reconfiguration.

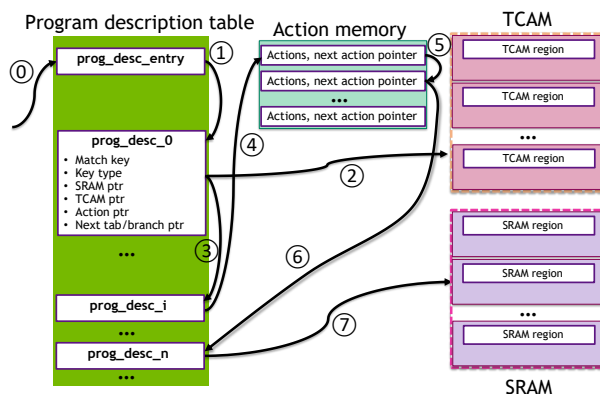
(iii) Indirection. FlexCore employs a partially disaggregated design, where each processor has a small amount of local SRAM to store a special *program description table (PDT)* for indirection. Accesses to PDT do not go through the crossbar and enjoy lower latency. PDT stores the 'program skeleton'—the control flow graph—and decouples the control flow operations from main SRAM accesses. Our partial recon-


Figure 2: Runtime reconfigurable tables and control flow branches, the indirection mechanism via the program description table (PDT), and an example execution as illustration.

figuration mechanisms make heavy use of the PDT to modify program elements. Similarly, a parser state table (PST) serves as indirection for the parsing hardware.

4 Runtime Reconfiguration Primitives

FlexCore introduces a set of novel primitives that, when invoked by the control plane, partially reconfigure a P4 switch program. These primitives operate on a graph representation of a P4 program by adding, removing, or modifying nodes and edges. In a P4 program, the match/action logic is captured by the 'table flow graph' [8], where nodes represent MA tables or conditional branches (realized in table-independent actions), and edges represent non-conditional, table dependency control flow. For the parser logic, the nodes represent parser states (which also contain header extraction rules), and the transition rules are the edges. Next, we first describe the primitives on the table flow graph and then the parsing graph.

4.1 Program description table

A key indirection data structure that enables partial reconfiguration of the table flow graph is what we call a *program description table (PDT)*, as shown in Figure 2. Each match/action processor maintains a local PDT and it is dedicated to a specific switch port. All packets arriving at a port will first hit a default entry in the PDT to activate packet processing.

The entries in the PDT are compiled from a P4 program. Each entry stores metadata about a *program element*, which could be a match/action table or a table-independent ALU action that implements conditional control flow. The metadata contains entry type, match key/type, and a resource pointer that refers to the physical realization of that program element. The pointer address could be an SRAM location (for exact and algorithmic ternary matches), a TCAM location (for ternary matches), or an action location (for conditional branches)—with a 'union' semantics as only one pointer type can be valid for a PDT entry. The address is specified by the base address of a memory region, the size of the region, as well as the offset from the base address. Each PDT entry also contains a 'next'

pointer, which encodes unconditional control flow to the next program element (i.e., MA table or conditional branch).

This indirection provides several advantages for runtime programmability: a) operations for adding and removing a program element are decoupled from resource allocation operations, as the first occur in the PDT and the second in the memory regions; b) PDT entries serve as a local scratch—entry modifications are lightweight and do not touch switch-wide shared resources, and they can be changed in a transactional manner. The PDT enables runtime reconfiguration of match/action tables and the control flow graph, which we discuss next.

4.2 Runtime reconfigurable tables

MA tables are the key processing elements in a P4 program. FlexCore enables the addition and deletion of tables using several partial reconfiguration primitives.

Allocation+deallocation. ALLOCTBL(T) allocates a new table, and DEALLOCTBL(T) deallocates an existing one. Both are control plane operations that have a centralized view of PDT tables, and they accept the table definition T as the input argument. Allocations first identify free slots to create new PDT entries. In a new PDT entry, the match key and type are filled in with the specified table attributes. SRAM and TCAM resources are then allocated based on the table attributes, and both are sharded across all memory banks. Finally, the control plane fills in the resource pointer, finishing the table allocation. Deallocations could directly remove the entry and its resources, or it may defer their removal to a later garbage collection phase. (Actual table entries are added/removed just like in today's switches, via existing control plane API such as that defined in P4Runtime [5].) Importantly, allocation/deallocation operations are not visible to network traffic until we invoke insertion/deletion primitives.

Insertion+deletion. Changes are made visible via another primitive: SETPTR(T,NXT) modifies T's next pointer to NXT. Table insertions invoke multiple SETPTR calls to place T in the program; deletions perform the opposite operations. Insertions must happen after resources have been allocated, and deletions before deallocation. Each pointer change is atomic in hardware. (To ensure atomicity for a collection of changes, we need another mechanism called a 'flex branch' as discussed later.) Insertions and deletions alter the view of the program state from the perspective of network traffic.

4.3 Runtime reconfigurable control flow

Conditional branches are implemented in ALUs as table-independent actions. Like tables, a conditional branch takes up one PDT entry, but its resource pointer addresses the action memory instead of SRAM/TCAM. In addition, the PDT entry for a conditional branch has a null 'next' pointer; its two jump addresses are instead encoded in the ALU action, one for each branch condition. N-way conditionals are implemented as cascading binary branches. Control flow branch
Figure 3: Primitives for in-place table modification.

modifications are performed using the following primitives.

Allocation+deallocation. FlexCore introduces a primitive, ALLOCCOND(B, PRED, BR$_1$, BR$_2$), to allocate a control flow branch based on PRED, where BR$_1$ and BR$_2$ are the jump addresses for the true and false branches, respectively. Allocation of an N-way conditional is performed by successive invocations of ALLOCCOND with cascading jump addresses. A predicate PRED corresponds to an ALU action that checks the condition and produces a true/false evaluation. This binary result is consumed by a hardware 'goto' microcode that jumps to the next program element. If PRED evaluates to true, 'goto BR$_1$' directs the control flow to the next table or a cascading branch; otherwise, it branches to BR$_2$. Deallocations free action memory and PDT entries.

Insertion+deletion. A conditional branch can be activated by a) SETPTR(T,B), which points a table's next pointer to the new branch B, and b) SETCONDPTR(B,N$_1$,N$_2$), which sets one or both of the jump addresses of a branch. In the case where SETCONDPTR modifies two pointers, the operation is not atomic. Atomicity is achieved similarly using 'flex branches' that we will discuss later. Deletions achieve opposite effects.

4.4 In-place table modifications

So far, all primitives that we have described can be used at any level of consistency guarantees. In this and the next subsections, we describe two special sets of primitives for table modifications and parser reconfigurations as well as their respective consistency properties.

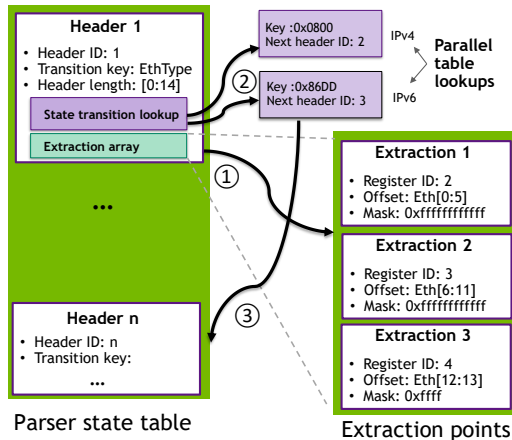
Table modifications can be performed by adding a new table and deleting the old, in which case the intermediate state has size $2 \times |T|$ (assuming both tables have size $|T|$). But FlexCore also exposes a more efficient primitive to reformat a table in-situ with an intermediate state of $|T|$. A MODTBL(T,T') primitive reformats T using the definition as specified in the new table definition T', which could include new match key/type and actions. This is achieved by a PDT mechanism called *table groups*. Several PDT entries can be 'grouped' together and processed in parallel at the MA processor. MODTBL creates a new PDT entry using T' and groups it with the entry for T. It then gradually moves entries from T to T', reformatting each entry using the new key or action, and setting the entries in T' with higher priority. In this transient state, the MA processor looks up both tables and resolves


Figure 4: Runtime reconfigurable parsers and the indirection mechanism via the parser state table (PST).

them using an *action resolver* that chooses the higher-priority result. When T become empty, the PDT entries are de-grouped and T gets deleted. MODTBL triggers simultaneous applications of parallel tables, so this mechanism is different from the 'flex branch'. We will discuss its consistency guarantees later in Section 4.6.

4.5 Runtime reconfigurable parsers

Header parsing logic requires different mechanisms for reconfiguration. We describe the parser hardware next, and then the reconfiguration primitives for the parser graph.

The parser state table (PST). Figure 4 presents the hardware architecture for the reconfigurable parser. The key indirection data structure is a *parser state table (PST)*, which stores an array of parser states. Each entry stores a) parsing information for that header, b) an extraction array that extracts header fields, as well as c) a parallel transition lookup component that determines the next state based on the current header values. Similar as the PDT, this indirection ensures that state additions and removals are easily achieved at runtime.

The PST implements a finite state machine, where each entry represents one state and contains transition rules to other states. This array is indexed by a logically assigned header ID that starts with one and ends with the maximum state ID as constructed from the program. When a packet comes in, it first matches against the default entry (ID=1) for parsing. At every step, the hardware uses the 'header length' and 'transition key' defined in the current entry (as well as a base register that remembers how much data has been parsed) to identify the correct offset into the packet. A chunk of data of the size 'header length' is then sent to extraction logic, which uses shift-and-mask to further segment the data chunk into multiple fields (e.g., EtherType, SMAC, DMAC) of varied sizes. These extracted fields are stored in an *extraction array* that is associated with the current header entry. These are further combined using a recombiner into a PHV (packet header vector) and streamed to the ingress blocks.

Simultaneously with header extraction, FlexCore uses a parallel set of logic to identify relevant headers to compute the next parsing state. This relies on a similar extraction logic but does not materialize header fields in the extraction array. Rather, it uses the preconfigured 'transition key' to perform a parallelized lookup. It muxes the key through a lookup table that contains all transition rules as compiled from the parser—e.g., IPv4 packets transition to ID=2, and IPv6 to ID=3. A demux combines the lookup results from all rules and computes the next state ID. Parsing continues until it encounters an accept state, at which point the extracted headers are sent to the ingress logic for MA processing.

Reconfiguration primitives. Runtime parser reconfiguration modifies the parser states, extraction rules, and transitions. FlexCore exports ALLOCSTATE(S), ALLOCTRANS(S1,S2), and ALLOCEX(R) for allocation of new states, transitions, and extraction rules, respectively. ALLOCSTATE(S) creates a new PST entry and the respective transition key and header length. ALLOCTRANS(S1, S2) sets up transition rules in the transition matching mux and demux. ALLOCEX(R) sets up an extraction rule in a parser state that locates a certain offset in the current header and outputs the result to an extraction register. Each primitive has its DEALLOC analogue.

Edits to the transition rules with ALLOCTRANS are immediately visible to network traffic, so for multiple changes, FlexCore requires the parser diff or the new parser to be prepared in PST scratch, before they are activated together in a single atomic step. Otherwise, network traffic will be parsed with a mix of old and new parsing logic. In the current hardware, parser changes are only possible with 'program consistency', which, as we will discuss later, requires higher resource headroom to maneuver. This limitation stems from the lack of a 'flex branch' equivalent in the current parser hardware, which is necessary for using the version metadata for transactions. In future hardware generations, this can be incorporated by adding transition version numbers as well as match logic using the versions.

4.6 Summary

We now discuss the two special-case primitives: table modifications and parser changes. MODTBL relies on 'table groups' instead of 'flex branches'. When a MODTBL operation is in progress, it guarantees that each packet is only processed with the old or new version of the table; in this sense, the intermediate states as seen by the packets satisfy 'execution consistency'. However, MODTBL cannot be parallelized with other program modifications, as 'table groups' do not atomically control which version is encountered by packets. Parser changes, on the other hand, satisfy program consistency; but the current hardware doesn't support weaker guarantees, which require 'flex branches'. In the next section, our reconfiguration algorithms primarily focus on changing MA tables and control flow branches, where all three consistency guarantees apply and are achievable at different overheads.
Figure 5: (a) FlexCore constructs a minimum common supergraph between two programs. (b) Weaker consistency guarantees reduce resource requirements for reconfigurations, and allow more intermediate states to be exposed to network traffic. (c) To ensure atomicity, FlexCore inserts 'flex branches' that can branch to the old or new versions depending on the version metadata. These branches are deleted after reconfiguration completes. Nodes A-F represent MA tables or conditional control flow branches. Virtual nodes r and s are added as the sources and sinks of the DAGs, respectively. Virtual nodes i denote flex branches.

5   Runtime Reconfiguration Algorithms

The FlexCore reconfiguration algorithms rely on the partial reconfiguration primitives to transform an existing switch program *prog* to a new one *prog**. We represent each P4 program as a directed acyclic graph (DAG), G for *prog* and G^* for *prog**. Nodes are the MA tables and conditional branches, and edges represent unconditional dependencies (or packet dataflow through the program). Our goal is to compute a *reconfiguration script* [9], a series of graph edit operations to nodes and edges to transform G into G^*. We denote the reconfiguration sequence as $G \to S_1 \to \cdots \to S_n \to G^*$, where $S_i, in \in [1..n]$ are the intermediate DAGs and each step from S_i to the next state is atomic. Depending on whether (or what types of) intermediate states are allowed to be exposed to network traffic, we propose three levels of consistency guarantees: program consistency, element consistency, and execution consistency, with a decreasing order of strictness. Stronger guarantees are achieved by preparing larger portions of the program diff in scratch memory, requiring that the switch resources must have enough slack for the reconfiguration. Weaker guarantees allow FlexCore to operate within more restricted headroom. Figure 5 includes an illustrative example.

5.1   Program consistency

This is the strongest level of consistency guarantees: no intermediate state is exposed to any packets. The switch program as encountered by network traffic is either G or G^*. This is important for any scenario that requires strong network processing guarantees, where exposing intermediate state would cause operational disruption. For instance, a load balancer or NAT may contain two match/action tables, one for mapping DIP to VIP and another for the reverse direction [25]. Updates to the program (e.g., rehashing) should not take effect until both tables have been reconfigured.

Program consistency. *A sequence $G \to S_1 \to \cdots \to S_n \to G^*$ achieves program consistency if the following property holds for all $S_i, i \in [1..n]$. For any element t (node or edge) in S_i, if $t \in G^*$ and $t \notin G$, then $S_i = G^*$. Similarly, for any element t*

in S_i, if $t \in G$ and $t \notin G^*$, then $S_i = G$.

Put in simpler terms, reconfigured program elements aren't visible to network traffic until all reconfigurations finish: an "all-or-nothing" guarantee. To achieve this, all edits must be prepared in an 'offline' scratch area. They are made visible in an atomic transaction that, from the packets' perspective, changes G to G^* in one single step. Without the partial reconfiguration primitives in FlexCore, one would need to instantiate the entire program *prog** in the scratch while the old one *prog* is still active. Therefore, the switch resources must have enough slack to accommodate the co-existence of both programs—i.e., there must be a headroom of $|G|+|G^*|$. Supposing that $|G| \approx |G^*|$, then the switch resource utilization must be kept to $\leq 50\%$ for runtime changes to be feasible. This is a stringent requirement.

Algorithm. Our new primitives enable FlexCore to only prepare the 'diff' while reusing shared program elements, so the switch only needs to accommodate $|G|$ and newly inserted elements of the size $\Delta \ll |G^*|$. In order to compute the diff, FlexCore merges two DAGs G and G^* into a *minimum common supergraph (MCS)* [9]. An MCS is the union of the input DAGs that minimizes the diff as caused by mismatched elements. In our context, only nodes take up resources and edges are pointer fields in the nodes and do not consume physical resources; so our MCS algorithm primarily extracts node-level diff. Using this MCS, we compute a set of edit operations as our reconfiguration script. INS(v) and DEL(v) inserts and deletes a node, respectively; and INS(e) and DEL(e) operate on edges. A special edge substitution operation XCH(e,e′) is allowed if both edges share the same source node and are of the same type (i.e., both are 'next' pointers or both are true/false jump addresses). In terms of resource overheads, INS(v) reduces and DEL(v) increases switch headroom by $|v|$, respectively, where $|v|$ is the table size (for MA tables) or action memory size (for conditional branches). Edge operations do not affect resource headroom. Figure 6 shows the algorithm, which colors the MCS: shared elements in black, new elements in green, and deleted elements in red.

```

    G ← MERGEDAGS(G, G*)
    // Compute reconfiguration script
    Script ← ∅
    for node or edge t ∈ G do
        if t ∈ G ∧ t ∈ G* then
            COLORBLK(t)
        else if t ∈ G ∧ t ∉ G* then
            COLORRED(t); Script.Add(DEL(t))
        else if t ∉ G ∧ t ∈ G* then
            COLORGRN(t); Script.Add(INS(t))
    Script.IdentifyEdgeXch(G)
    return Script
```

Figure 6: The program consistency algorithm.

Atomicity. To ensure that intermediate states are not visible until all reconfigurations complete, FlexCore groups the edits in a transaction to achieve atomicity. We use a hardware mechanism that we call a *flex branch*. During the transaction, inserted program elements are guarded by an extra conditional branch that implements a check on special version metadata: 'if (meta.v==0)' branches to the old program elements and 'if (meta.v==1)' to the new. Deletions are also guarded by flex branches instead of being deleted right away. The transaction is committed when FlexCore modifies the version metadata, after which deleted elements can be safely removed.

5.2 Element consistency

A relaxed consistency guarantee, which allows reconfigurations to proceed within more restricted headroom. In program consistency, preparing the diff in scratch area leads to a resource spike of Δ. Therefore, in order to accommodate runtime reconfigurations, the switch utilization must be upper-bounded to leave sufficient headroom Δ.

Element consistency breaks the reconfiguration into several finer-grained transactions that can be performed with lower headroom δ ≪ Δ. This allows FlexCore to drive up switch utilization even further while still preserving the ability to make runtime reconfigurations. Every smaller transaction will add and remove certain program elements, with the goal of releasing some switch resources to accommodate subsequent transactions. Under this guarantee, intermediate states can be exposed to traffic, but only if there is a consistent view as to which program elements have been updated (inserted or deleted). If program elements (nodes or edges) are reachable from each other, they must be updated together. Unreachable edits are partitioned to different transactions as they are independent from the view of network traffic. This property is useful when program updates can be applied incrementally with well-defined semantics. For instance, a firewall that uses independent ACL tables for different types of traffic (e.g., TCP vs. UDP) can be added or removed on a table-by-table basis. A traffic normalizer [1, 22, 39] may apply different

```
function ELEMENTCONSISTENCY(prog, prog*)
    // Compute overall script
    Script ← PROGRAMCONSISTENCY(prog, prog*)
    // Reachability analysis. Optimization using Xch operations.
    for all Xch(u→v, u→v′) ∈ Script do
        u.Reachability ← DFS(u, G)
    // Partition script by reachability
    Partitions ← INITPARTITIONFOREACHEDIT(Script)
    while ∃ reachable partitions p, q do
        MERGEPARTITIONS(p, q)
    return Partitions
```

Figure 7: The element consistency algorithm.

security functions for incoming and outgoing traffic—e.g., normalizing TTL fields for incoming packets, but clearing TCP options for outgoing ones.

Element consistency. *For any intermediate state $S_i, i \in [1..n]$, we require the following properties to hold. For any element t in S_i, if $t \in G^*$ and $t \notin G$, then for any other element t' in G^* where $t' \rightsquigarrow^* t$ (i.e., t' can reach t in G^*) or $t \rightsquigarrow^* t'$, we require that $t' \in S_i$. Similarly, for any element t in S_i, if $t \in G$ and $t \notin G^*$, then for any other element t' in G where $t' \rightsquigarrow t$ (t' can reach t in G) or $t \rightsquigarrow t'$, we require that $t' \in S_i$.*

Stated simply, if a new program element is visible in the intermediate state, it should be visible to all packets that traverse this element in the new program, even if they follow different execution paths through the program. A deleted element is no longer visible to packets regardless of their execution paths.

Algorithm. As Figure 7 shows, we first invoke the program consistency algorithm to compute the overall reconfiguration script, and then partition this script into independent, smaller transactions. This relies on a DFS search on **G** to compute whether one edit may affect another. If two edits operate on unreachable regions of the graph, they may proceed independently; otherwise they belong to the same partition. Initially, each edit is in its own partition. Partitions are merged if they are reachable from one another—*p* and *q* are said to be reachable if their edit operations involve elements that are reachable in either direction in **G**. This implies that the algorithm scales quadratically with the number of edit operations.

Although we can perform DFS from all nodes and edges in **G** in polynomial time, in practice we only need to do so from nodes that are involved in an XCH operation. This computes all needed reachability information to merge the partitions, because such nodes are the boundaries between the new and old graphs. Red nodes/edges are reachable from at least one such XCH node by following its red outgoing edges, and similar properties hold for the green color. When no further merges are possible, the algorithm returns a partition of the reconfiguration script.

Atomicity. Each smaller transaction begins with 'meta.v==0'. Flex branches guard intermediate changes or make them visible by changing 'meta.v'. The reconfiguration finishes after all constituent transactions are committed.

```
function EXECUTIONCONSISTENCY(prog, prog*)
    // Compute overall script
    Script ← PROGRAMCONSISTENCY(prog, prog*)
    // Bounded reachability analysis

```

Figure 8: The execution consistency algorithm.

5.3 Execution consistency

We next consider an even more relaxed guarantee with more finer-grained transactions. Under execution consistency, a new program element may only be visible to some execution paths but not others. Likewise, if an element is deleted from some execution paths, other executions may still use this element until all reconfigurations finish. Such intermediate states are still consistent in that a packet never experiences an execution path that mixes old and new elements. This is the weakest level of consistency that we consider in FlexCore. It is a suitable guarantee for program changes that are in nature non-disruptive—e.g., functions that do not interfere with packet processing decisions, or functions where inaccuracy is tolerable. For instance, a telemetry module that samples or aggregates traffic can be added or removed using execution consistency. The intermediate states merely introduce noise to the monitoring data, but do not break functionality.

Execution consistency. *For any intermediate state $S_i, i ∈ [1..n]$, any execution path through this program, $p ∈ S_i$, should satisfy that $p ∈ G$ or $p ∈ G^*$.*

This allows reconfigurations to proceed at a per execution path basis. Paths are added to the program as a whole, or they are deleted as a whole. But packets will not encounter partial paths or paths that mix old and new elements.

Algorithm. Figure 8 shows the pseudocode. As before, we perform a reachability analysis from Xch nodes; but unlike in element consistency, the DFS terminates when encountering other Xch nodes or shared (black) nodes. The visited elements form a subpartition for each Xch node. In element consistency, if Xch1 reaches Xch2, they are merged into the same transaction. But execution consistency only requires the merge of certain Xch regions, but not all. If independent reconfigurations of Xch1 and Xch2 do not lead to partial or mixed paths, then their edits can be performed separately.

Specifically, we analyze the ordering relation between all pairs of Xch nodes. If Xch1 can reach Xch2 via a green (new) path p_g, then reconfiguring Xch1 before Xch2 will lead to a situation where the part of p_g in Xch1 is activated but its extension into Xch2 is not, leading to a mixed path. Reconfiguring Xch2 before Xch1, on the other hand, is safe because the changes are not reachable from Xch1. Of course, this reconfiguration will not enable p_g, but this may enable other paths elsewhere so it is a valid plan to be considered. Similarly, if Xch1 reaches Xch2 via a red (old) path p_r, then reconfiguring Xch2 before Xch1 will delete p_r from its end while its earlier part is still in use, resulting in mixed colors. Reconfiguring Xch1 before Xch2, on the other hand, is valid because it simply removes p_r. If Xch1 can reach Xch2 via green and red paths, then the only valid plan is to reconfigure both regions atomically.

This above ordering relation generates a set of constraints across Xch nodes, as well as an ordered set of subpartitions. These subpartitions are finer-grained than the partitions in element consistency, so they enable smaller transactions. One final care must be taken: since subpartitions may be reachable from each other, the bounded DFS may reach shared elements from different Xch nodes. The edit operations in two subpartitions, therefore, may have overlaps. A deduplication step over the subpartitions ensures that a deletion operation is deferred to the last subpartition where the deleted element is used, and that an insertion operation is performed in the first subpartition where the new element occurs. This concludes the execution consistency algorithm, whose complexity is quadratic with regard to the number of Xch nodes.

Atomicity. The use of flex branches makes each subpartition visible to network traffic atomically. The entire transaction finishes when all subpartitions have been reconfigured.

5.4 Summary

The reconfiguration script is then realized by the partial reconfiguration primitives in Section 4—e.g., an operation on v will translate into a table or branch operation depending on v's type. For program consistency, all edits are applied in one single, atomic step, but for element and execution consistency, the (sub)partitions are applied sequentially. This raises another consideration as to the ordering of the transactions in the latter two algorithms to minimize the maximum utilization peak. We perform an exhaustive search over the order. This search terminates when it has identified a feasible order or when it concludes that no such order exists.

6 Limitations and Discussions

Program equivalence. The FlexCore partial reconfiguration primitives and algorithms operate on P4 program elements, relying on the structural differences between two P4 programs. It currently doesn't analyze whether structurally different programs may have the same semantics [10, 13], which is an interesting avenue for future work.

Stateful packet processing. FlexCore currently does not support stateful switch programs. The P4 standard defines persistent state as an "extern" feature that is up to the individual architectures to implement (e.g., registers in PSA). Partial reconfiguration of stateful features raises additional questions as to how network state should be ported to the new program, e.g., with programmer-supplied state transformation functions, much like in SDN software controller upgrades [32].

Resource headroom. The FlexCore algorithms require that the switches have sufficient resource slack, but there could be scenarios where even the weakest consistency would require more resource headroom than available. To address this, one could relax execution consistency even further to capture which types of 'mixed' executions are still semantically meaningful; alternatively, one could also migrate certain resources to other devices to make room for the reconfiguration.

Other architectures. The FlexCore primitives target P4 program changes, so they are in principle architecture-independent. The dRMT variant that FlexCore uses makes runtime reconfiguration particularly natural, but most P4 targets have some degree of runtime flexibility. The RMT architecture, for instance, may be augmented with the ability to reconfigure each stage independently. Software switch targets (e.g., for the host or NIC) expose even more runtime flexibility than switch ASICs. Although the original dRMT project [11] didn't provide an ASIC implementation, we believe that our indirection structures are compatible with its outlined design.

Other languages. FlexCore's reconfiguration primitives target P4 programs, but for other languages (e.g., NPL [2], PoF [36]), one should be able to develop analogous reconfiguration primitives based upon their respective language features. The property of runtime programmability is not tied to a specific language.

7 Implementation

We have implemented FlexCore in several components. The reconfiguration primitives are implemented by manipulating the hardware ASIC control registers via the PCIe interconnect from the control plane. The indirection structures are implemented in the Spectrum-2 silicon design, and FlexCore is the first effort to leverage them for runtime, partial reconfiguration. Our compiler uses p4c [4] as the frontend; it implements incremental compilation of P4 program elements, generating an individual binary image for each component, instead of outputting a monolithic binary for the entire program. The consistency algorithms are implemented at the control plane.

The hardware cost to enable runtime programmability comes from the use of indirection structures, including the PDT and PST. The PDT supports full reconfigurability at all consistency levels, but the PST only supports program consistency. We estimate the cost of the current PDT and the cost for making the PST fully reconfigurable at runtime.

Each MA processor has a local PDT, which holds roughly 1k entries—i.e., the largest P4 program it supports should have no more than ∼ 1k MA tables and conditional branches. The ASIC supports up to 128 MA processors overall. Recall the PDT format as shown in Figure 2: each entry contains a) a description of the match key, b) entry type (SRAM/T-CAM/Actions), c) resource pointer, and d) next table/branch pointer. In the worst-case scenario, each MA table has a different key, resulting in 1k distinct keys that the switch needs to support; this requires 10 bits to represent each distinct key in the PDT entry. The entry type field distinguishes between three types, requiring 2 bits. The resource pointer requires 20 bits, which is able to index one million distinct memory lines for SRAM/TCAM/Actions, roughly 20MB in size (the 'main database'). The next table/branch pointer requires 10 bits to index another PDT entry as the next hop. Overall, each PDT entry requires 42 bits, each PDT table consumes 5.25kB for 1k entries, and across 128 PDT tables the hardware overhead is 0.67MB, or 3.3% of the main database. The flex branch mechanism is implemented using existing ALUs, so it doesn't require dedicated hardware. For the PST, the Spectrum-2 parser hardware only supports runtime reconfiguration at program consistency level. This does not contain the 'flex branch' equivalent and the 'version' support for transition rules, which would be necessary for other consistency levels. We estimate the overhead of these additional structures to be under 1% of the main database.

8 Evaluation

We present a comprehensive evaluation of FlexCore, by applying our design to a 12.8 Tbps hardware ASIC and also a software simulator (a fork of bmv2) that has been integrated with the same reconfiguration primitives. To evaluate scalability, we have used a set of synthetic and real-world P4 programs. To synthesize the P4 corpus, our tool takes a specified program size and generates a random control flow graph. For real-world programs, we have used switch.p4, NetCache [19], and NetHCF [23], which represent large, medium, and small programs, respectively. The program edits are also generated randomly, which may mutate, insert, remove, or swap program elements. The edits are controlled by a parameter α, the reconfiguration ratio. If a program has 100 program elements, and a reconfiguration adds, removes, or exchanges 10 of them, we say that α = 10%. To evaluate realistic reconfiguration scenarios, we perform case studies using switch-based multicast, telemetry, attack mitigation, and tenant-specific extensions, on hardware and software platforms.

8.1 Reconfiguration primitives

We start by measuring the number of hardware operations that each reconfiguration primitive involves. These primitives are invoked by the control plane, and they modify a memory-mapped region of the PCIe device (i.e., the data plane). The PCIe bus sustains a peak throughput of ∼1 million operations per second. The control plane, however, is bottlenecked by the software speed; each operation took several milliseconds to
(a) NetHCF (V=43, E=58).　　(b) NetCache (V=109, E=129).　　(c) switch.p4 (V=168, E=242).

Figure 9: Scalability of FlexCore on three real-world programs. V: number of nodes, E: number of edges.
(a) Turnaround time　　(b) Number of primitives

Figure 10: The FlexCore algorithms scale well.

complete with software overhead. Table 1 shows the number of hardware register DWORD writes for each reconfiguration primitive. As we can see, table operations are the most heavyweight, control flow branch operations follow, then parser operations, and finally, edge edits complete within one write and are atomic. Deallocations have the same number of operations as their allocation analogues.

Primitive	RegAccess	Primitive	RegAccess
ALLOCTBL	112	GROUPTBL	112
ALLOCCOND	43	ALLOCSTATE	22
ALLOCTRANS	5	ALLOCEX	3
SETPTR	1	SETCONDPTR	2

Table 1: The number of hardware register accesses (in DWORDS) for each reconfiguration primitive. Allocation and deallocation primitives as measured only operate on metadata (i.e., PDT and PST), not including SRAM/TCAM/action memory resources. The cost for the latter varies depending on the allocation/deallocation sizes.

8.2 Consistency algorithms

Synthesized programs. We evaluate the scalability of FlexCore in generating reconfiguration scripts for programs of different sizes. We generated 100 programs of each size (800 in total), and set $\alpha = 40\%$ for FlexCore to generate reconfiguration scripts. Figure 10a shows the results. As expected, program consistency took the least amount of time, as the only analysis is on the program diff; all edits are then grouped as a

whole. The turnaround time for element consistency grows roughly quadratically with regard to the program size (more strictly, to the size of the diff, which is fixed to 40% of the program size). Execution consistency algorithm lies in between, as it scales with the number of Xch nodes, which is smaller than the program diff. Overall, FlexCore generated reconfiguration scripts for all programs within one second.

Next, we measure the number of invocations of the partial reconfiguration primitives as well as the version metadata operations. As shown in Figure 10b, the numbers of operations for different consistency levels are roughly the same. This is because the number of reconfiguration operations are the same regardless of the consistency level. But the number of transactions increases for weaker guarantees due to the extra version metadata operations.

Real-world programs. We then tested FlexCore on three real-world programs of different sizes, and further varied the reconfiguration ratio α from 5% to 50%. As Figure 9 shows, the FlexCore turnaround time is longer for larger programs and higher reconfiguration ratios. But the overall takeaways are similar as before: FlexCore algorithms scale well for computing reconfiguration scripts. In the Appendix, we further include scalability results for ordering the transactions.

Consistency levels. Figure 11a shows the CDF of the transaction sizes under different consistency guarantees for the synthetic programs with different sizes and α. Under stronger consistency guarantees, the transactions have larger sizes (we fix all tables to the same size). We also measure the headroom requirements. Figure 11b visualizes the step-by-step reconfiguration for one such program: program consistency requires a large peak headroom, but weaker guarantees have less stringent requirements. All consistency levels eventually converge to the same utilization level after reconfiguration completes. Figure 11c tests another program in the software simulator, which plots the percentage of traffic that experiences the old program after the first update is enabled during the reconfiguration under different consistency levels. As we can see, program consistency does not expose any intermediate state, but weaker guarantees lead to more traffic that is

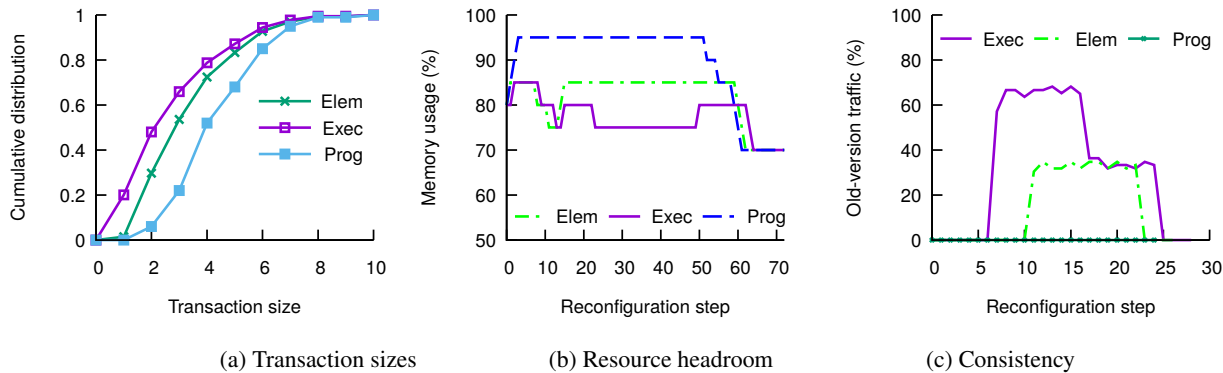
(a) Transaction sizes   (b) Resource headroom   (c) Consistency


Figure 11: (a) Weaker consistency guarantees lead to smaller transaction sizes; they require lower resource headroom, but more traffic will encounter the old program during reconfiguration. In (b), the initial switch utilization when the reconfiguration starts is 80%. In (c), we use a program whose control flow graph is presented in Figure 5; Y-axis shows the traffic ratio processed by the old program after the first reconfiguration transaction is committed at the 6th step.

processed using the old program during the reconfiguration.

8.3 Case study: Accelerated multicast

Just-in-time optimization. Next, we present a case study using the hardware ASIC, where program elements are injected to the switch pipeline at runtime to accelerate multicast applications. Initially, the switch is configured with a baseline program without any multicast optimizations, and it connects one ZeroMQ unicast sender and multiple receivers. Just before the ZeroMQ application starts, we initiate a partial reconfiguration to extend the switch program with Elmo [34], a switch-based multicast function. Elmo performs source-routed multicast in hardware with customized protocol headers to improve scalability. After ZeroMQ finishes, another reconfiguration removes the Elmo components from the switch pipeline. These changes are performed under program consistency. Each reconfiguration took less than 0.5 s to complete in control plane software.

Just-in-time telemetry. Just before removing Elmo, we inject a co-located telemetry application to observe the effect of Elmo removal, by monitoring the average pipeline latency of randomly sampled packets. This telemetry application is unloaded after the removal of Elmo.

Reconfiguration. Figure 12a plots the throughput of a third background iPerf application during the entire reconfiguration. As we can see, the reconfigurations did not cause any service interruption, as the iPerf throughput was stable throughout the experiment; the switch drop counters also showed no packet loss. Figure 12b plots the additional resource usage in terms of PDT memory, PST memory, and table entries during the runtime reconfigurations. The insertion of Elmo caused a resource usage increase, as did the insertion of the telemetry application. But in both cases, the extra resource overheads for PDT and PST are under 200 bytes. Table rules for multicast and telemetry, on the other hand, are the dominant overheads. All resources are released after the program modules are removed from the pipeline.

Performance. Figure 12c shows that the injection of Elmo improves multicast scalability, where we measure the completion time to send 200 k ZeroMQ messages. Before injecting Elmo, a preceding ZeroMQ run via unicast took up to nearly 60 seconds for six receivers; and the completion time grows roughly linearly with the number of receivers. After injecting Elmo, the switch-based multicast scales independently of the number of receivers, finishing at roughly 20 seconds across all tested configurations. The injected telemetry application detected that the pipeline latency experienced a 20 ns decrease after Elmo was removed from the pipeline.

8.4 Case study: Dynamic telemetry upgrade

In-place application upgrade. We perform another ASIC-based case study under execution consistency. The operator modifies the telemetry application discussed earlier to use different flow keys. Initially, the application uses the IPv4 five tuple as the match key and is configured with 30 k entries. Packets of interest are sampled to software for telemetry processing. The operator issues a reconfiguration to modify the match key to the source and destination addresses instead, using the MODTBL primitive. This modification also reduces the resource usage, as entries become smaller.

Reconfiguration. Figure 13 plots the performance of a background iPerf application, which shows stable throughput. The blue area further shows an additional IPv4 test trace that we generated to specifically trigger the telemetry table. The switch counters indicated zero packet loss for iPerf and the IPv4 test traffic. We have set the migration rate to be 3k entries per second, so the modified table was populated in ~10s. The PDT operations at the control plane software took 400 ms.

Utilization. Figure 14 shows the intermediate program sizes using MODTBL, and compares it with the baseline that inserts the new table and then deletes the old. The baseline incurs a resource utilization spike, which occurs when both tables are co-resident in the switch. As the old table is gradually deallocated, the resource usage drops to the size of the new

(a) Hitless reconfigurations.

(b) Resource overheads.

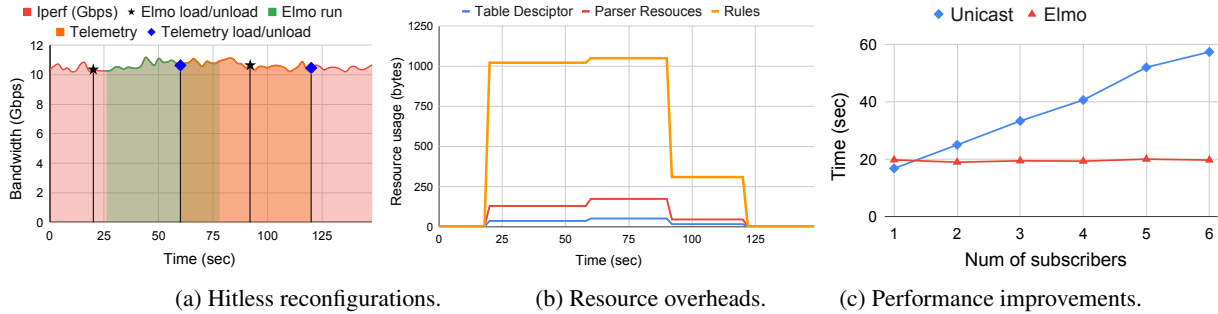
(c) Performance improvements.


Figure 12: FlexCore inserts Elmo, a switch-based multicast program, just-in-time to accelerate ZeroMQ performance. It also inserts a telemetry application to observe the effect of the removal of Elmo.

table. The final SRAM usage shows the resource reduction in changing the flow keys. In contrast, our in-place modification consistently reduces resource usage reduction right from the beginning, until resource usage approaches its final state.

8.5 Simulator case studies

We have performed two case studies in the software simulator with element consistency. The appendix includes concrete results. We highlight here that all reconfigurations were effective and free of interruptions.

Real-time attack mitigation. This case study injects a *TCP normalizing firewall* [1] and a *covert channel defense* [39] upon attack detection. The normalizer pads all TTL values to avoid inconsistent views at host IDS [22], and the covert channel defense clears TCP reserved bits to avoid data leakage [39]. The normalizer inspects incoming traffic, but the covert channel defense inspects outgoing traffic.

Tenant-specific network extensions. VM migration triggers FlexCore to carve out the tenant's ACL functions from the original switch and inject it to the destination switch.

9   Related work

Programmable networks. Network programmability has been a longstanding goal in the community—starting with 'active networks' [6, 33, 37], each step in this direction has led to significant innovation in the networking ecosystem. FlexCore takes the next step to enable *runtime programmable switches*. Recent projects P4Visor [42] and Hyper4 [16] also use DAG merging algorithms on P4 programs, but our focus is on partial program reconfiguration.

Consistent updates. Network updates are common to datacenters [20, 28], and ensuring the absence of service interrupt is a key goal [24]. Researchers have considered live migration of BPG sessions and virtual routers [21, 38], and per-packet and per-flow consistency guarantees for OpenFlow network updates [29, 30]. Our work tackles the problem of achieving reliable switch program updates at runtime, and proposes a new set of consistency guarantees.

OS+network specialization. The vision of FlexCore is inspired by prior work in OS and network specialization. SPIN [7] is an OS that allows applications to inject safe and dynamic extensions to the kernel. Exokernel [14] enables applications to specialize OS functions at user level. ESwitch [26] specializes OpenFlow software data planes to achieve higher performance for a given workload. Our work aims to enable similar goals for programmable switches.

10   Conclusion

FlexCore argues that runtime programmability should be a first-order goal in future networks, allowing functions to be added or removed dynamically. FlexCore contributes design considerations on switch architectures, partial reconfiguration primitives, reconfiguration algorithms and consistency guarantees. Our evaluation shows that the FlexCore reconfiguration algorithms are scalable, and that runtime reconfigurations are beneficial and free of disruption.

11 Appendix

11.1 Case study: Real-time attack mitigation

In this case study, we present how FlexCore facilitates real-time attack mitigation by reconfiguring two defense functions to the software switch simulator.

Traffic normalizers [22] are firewall utilities that prevent inconsistent views between network IDS and end hosts. As an example, some packets may be seen by the IDS, but their TTL values are crafted in such a way that they are dropped soon after the network IDS and do not trigger processing at end hosts. This leads to vulnerabilities [22]. A normalizer firewall can pad TTL values to ensure that the IDS and the hosts always have the same view.

Covert channels [39] leak secret data by repurposing packet header fields as data carrier. For instance, an attacker that compromise a server that hosts confidential data may leak the secret by padding them into the TCP reserved bits of network traffic. A defense needs to clear such optional header fields to prevent leakage.

Real-time attack mitigation. In our case study, we inject a *TCP normalizing firewall* [1] and a *covert channel defense* [39] upon attack detection. Since these two defenses are independent, they can be reconfigured under element consistency. Figure 15 shows the workflow for the reconfiguration. After each defense is deployed, the attack traffic can be recognized and blocked; its throughput drops to zero. The normal traffic does not experience any loss or interruption during the reconfiguration.

11.2 Case study: Tenant-specific network extensions

In this case study, we focus on multi-tenant datacenters where each tenant can inject her own network extensions to the switch. Upon VM migration, the switch modules are carved out from the source and grafted to the new destination switch.

Program grafting in VM migration. In this scenario, a tenant has her ACL module injected to the ToR switch, and her VM migration will bring this module to a different destination rack. This is achieved by carving out the ACL components and grafting them to the destination switch using partial reconfigurations. Figure 16 shows the traffic rate of the tenant's traffic and the background traffic. The migration is achieved in several steps. It first inserts the ACL module to the new switch, and then routes traffic to the new switch by updating the routing rules of upstream switches. Finally, it removes the ACL module in the old switch. As we can see, the migration does not cause throughput drops of the background traffic during the reconfiguration, and the tenant's traffic is migrated to the new switch without service interruption.

11.3 Evaluation: Ordering the transactions

For element and execution consistency, the reconfiguration proceeds in multiple steps. So FlexCore additionally performs an exhaustive search to identify a feasible sequence under the current headroom. The problem can be stated as: given
Figure 15: Simulation traffic rates (ST) when reconfiguring the switch using element consistency to inject real-time network defenses.
Figure 16: Simulation traffic rates (ST) during a reconfiguration triggered by VM migration, which carves out an tenant-specific ACL module from the source switch and grafts it to the destination switch.

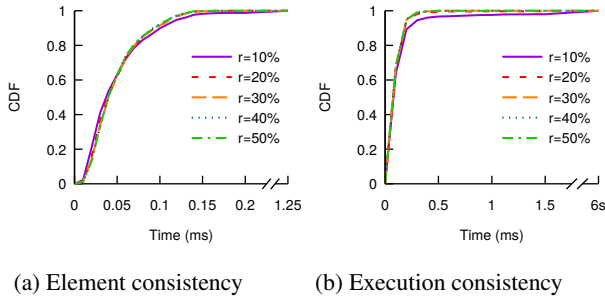
(a) Element consistency   (b) Execution consistency


Figure 17: The turnaround time for finding a feasible sequence for the transactions, under element and execution consistency.

a set of transactions $tx_1, tx_2, \cdots, tx_k$, find a feasible sequence that fits into the current resource headroom, or conclude that such a sequence doesn't exist. For element consistency, the transactions do not have a hard constraint as to their order. The search only focuses on optimizing for resource headroom. Execution consistency has hard constraints as to which transactions should be ordered before others. The search also encodes such constraints as induced from the XCH nodes.

In Section 8.2, we have evaluated the scalability of the algorithm in generating reconfiguration scripts. Here, we further evaluate the turnaround time for identifying a feasible sequence of transactions that can be applied within the available headroom. We have used an α ranging from 10% to 50% on the synthesized programs, and tried different switch resource

headrooms as denoted by r (ranging from 10% to 50%).

Figure 17a shows the results for element consistency. We can see that FlexCore finishes within 0.2ms for all programs across different headrooms except for r=10%. With 10% headroom, the switch has very small slack for the reconfiguration, so it takes more time to search for a feasible plan or determine that no solution exists.

Figure 17b shows the results for execution consistency, where the turnaround time is higher because of two reasons. First, execution consistency needs to merge and deduplicate the subpartitions following their constraints. Second, execution consistency could generate more candidate solutions, resulting in longer searching time. However, the algorithm can still complete within 1.5ms for 98% programs and within 6s for all programs.

IMap: Fast and Scalable In-Network Scanning with Programmable Switches

Abstract

Network scanning has been a standard measurement technique to understand a network's security situations, e.g., revealing security vulnerabilities, monitoring service deployments. However, probing a large-scale scanning space with existing network scanners is both difficult and slow, since they are all implemented on commodity servers and deployed at the network edge. To address this, we introduce IMap, a fast and scalable in-network scanner based on programmable switches. In designing IMap, we overcome key restrictions posed by computation models and memory resources of programmable switches, and devise numerous techniques and optimizations, including an address-random and rate-adaptive probe packet generation mechanism, and a correct and efficient response packet processing scheme, to turn a switch into a practical high-speed network scanner. We implement an open-source prototype of IMap, and evaluate it with extensive testbed experiments and real-world deployments in our campus network. Evaluation results show that even with one switch port enabled, IMap can survey all ports of our campus network (i.e., a total of up to 25 billion scanning space) in 8 minutes. This demonstrates a nearly 4 times faster scanning speed and 1.5 times higher scanning accuracy than the state of the art, which shows that IMap has great potentials to be the next-generation terabit network scanner with all switch ports enabled. Leveraging IMap, we also discover several potential security threats in our campus network, and report them to our network administrators responsibly.

1 Introduction

Network scanning is a typical procedure to discover active hosts, ports and services in a network, which is mainly used by network operators/researchers for security assessment and system maintenance of the network. Enabled by tools such as Nmap [39], ZMap [14] and Masscan [33], network scanning has become a standard measurement technique to understand host behaviors in the target network, even the entire Internet.

Recent studies have demonstrated that network scanning can help reveal new security vulnerabilities [3, 6, 10], monitor service deployments [2, 13, 20, 42] and shed light on previously opaque distributed systems [19], which are essential for people to understand the network's security situations.

Today's network scanners, however, cannot keep pace with today's soaring scanning space and provide a timely security snapshot. Recently IPv6 has proceeded to the stage of large-scale deployment, and reports show that IPv6 is used by 18.7% of all the websites [47]. Along with the adoption of 5G networks, more and more Internet-of-Things (IoT) devices and mobile devices are connecting online [4]. The increased address space and the numerous online devices mean that the network scanner should be *scalable* to this much larger scanning space easily. Moreover, since these IoT and mobile devices go online and offline frequently, it is necessary for network scanners to conduct a comprehensive scanning quickly. Otherwise, a large number of security snapshots cannot be captured, potentially missing numerous security incidents [46]. This raises the requirement that the network scanner should complete a comprehensive scanning as *fast* as possible.

However, a closer look into today's network scanners shows that they are far from being fast and scalable due to their implementation targets and deployment locations. First, in terms of implementation targets, current network scanners are all implemented on commodity servers. As CPUs on servers are not specialized for high-speed packet processing, the scanning speed of these CPU-based network scanners is intrinsically limited. Second, in terms of the deployment locations, state-of-the-art network scanners are all located at the network edge. Scanning from the edge is usually limited by the upstream bandwidth of the end host, which inevitably constrains the utmost scanning speed for network scanning tasks. Besides, the end-to-end scanning paths indicate more bandwidth waste for edge networks and larger possibilities of dropping probe/response packets.

In this paper, we propose IMap, a fast and scalable in-network scanner to address the aforementioned issues. The technology enabler for IMap is the emergence of pro-

grammable switches [9], which offer unprecedented programmability and flexibility without sacrificing performance. Generally speaking, one single programmable switch could provide a packet processing capability as high as multiple Tbps, which is several orders of magnitude higher than highly-optimized servers. Besides, such switches support stateful packet processing with domain-specific languages (e.g., P4 [8]), which allows programmers to enforce user-defined packet processing logics in the switch pipeline directly. Moreover, switches (especially core switches) provide a unique vantage point for network scanning, which is no longer constrained by the upstream bandwidth of the end host or plagued by the bandwidth waste of the end-to-end scanning paths. These unique characteristics of programmable switches are incredibly valuable for the next-generation fast and scalable network scanners.

Nevertheless, designing IMap is a non-trivial effort. As an in-network scanner, when sending probe packets, IMap must cover the scanning space completely, and also be aware of network conditions to avoid affecting the normal packet routing functionality. Besides, once response packets arrive, IMap should distinguish normal packets and response packets correctly, and also process the response packets efficiently to avoid saturating the storage server. However, switches only have constrained computational models and limited memory resources, which cannot satisfy these requirements easily.

To meet these requirements, IMap designs a set of techniques and optimizations, i.e., an address-random and rate-adaptive probe packet generation mechanism, and a correct and efficient response packet processing scheme, to turn a switch into a high-speed network scanner. We implement a prototype of IMap in an Intel Tofino switch [23], and make the source code publicly available [22]. Testbed experiments and real-world deployments show that even with one switch port enabled, IMap can survey all ports of our campus network (i.e., 6 Class B IP Addresses), a total of up to 25 billion scanning space, in 8 minutes, achieving a nearly 4 times faster scanning speed and 1.5 times higher scanning accuracy than state-of-the-art network scanners. IMap also discovers several potential security threats in our campus network. To the best of our knowledge, IMap is the first network scanner that can potentially reach multiple Tbps scanning speed, benefiting from its implementation targets and deployment locations. We hope IMap can serve as the foundation for next-generation terabit network scanners.

In summary, we make following contributions in this paper:

- We analyze the limitations of current network scanners, and identify the opportunities brought by programmable switches (§2).

- We propose IMap, a fast and scalable in-network scanner with programmable switches. IMap consists of a probe packet generation module to generate high-speed probe packets with random address and adaptive rate, and a

response packet processing module to process response packets correctly and efficiently (§3, §4).

- We implement an open-source prototype of IMap, and conduct extensive testbed experiments and campus network deployments to show advantages of IMap (§5, §6).

Finally, we make some discussions in §7, describe related works in §8, and conclude this paper in §9.

2 Motivation and Observation

2.1 Limitations of Current Network Scanners

With the rapid growth of scanning spaces and security incidents recently, today's network scanners are falling behind the times, especially in terms of scanning *scalability* and scanning *speed*. First, network scanners should be able to scale to large scanning spaces easily. Recently IPv6 has been in the stage of large-scale adoption, for instance, Google's statistics show that around 35% of its users access Google via IPv6 [24]. Since IPv6 has a much larger address space than IPv4, the scanning space increases drastically. Besides, along with the deployment of 5G networks, more and more IoT/mobile devices are connecting online [4]. All these require that network scanners should be able to cover a large scanning space easily. Second, network scanners should be fast enough to provide timely security snapshots. Today's networks become more and more dynamic, and IoT/mobile devices switch between online and offline frequently. Meanwhile, we have also witnessed that security incidents occur more and more frequently, and some of them occur in a very small time scale (e.g., from tens of seconds to several minutes). For example, according to Cybint's monthly newsletter, since COVID-19, the frequency of cybercrimes increases 300%, and hackers attempt to attack vulnerable home networks as people are working from home [46]. As a consequence, network scanners should be able to complete a comprehensive scanning as fast as possible. Otherwise, some security snapshots cannot be captured and important security incidents may be missed.

However, today's network scanners are intrinsically slow, which are far from being fast and scalable to satisfy the aforementioned new requirements. For example, with Zippier ZMap [1], one of the most powerful network scanners today, the scanning capability only reaches a throughput of 10 Gbps and a rate of 14.2 Mpps [45]. The capability of today's network scanners is limited by two key factors fundamentally. First, in terms of implementation targets, current network scanners are all implemented on commodity servers. Packet processing on commodity servers is intrinsically slow, since CPUs are not specialized for high-speed packet processing. Even with software optimizations like DPDK [12], the throughput cannot reach more than 40 Gbps easily [25,41,50]. Second, in terms of deployment locations, today's network scanners are all located at the edge of the network. Scanning

from the edge is not only limited by the upstream bandwidth of the end host, but also incurs longer scanning paths and non-negligible bandwidth waste because of end-to-end scanning paths. As a result, even the scanners are capable of scanning at higher rate (e.g., 40 Gbps), the scanning results (e.g., hit rate, active/inactive rate) may suffer from low accuracy because of undesirable probe/response packet drops on the end-to-end scanning paths (§6.2). Not surprisingly, because of these fundamental limitations, since the publication of Zipper ZMap [1], the network scanning tools have not experienced any progress, and researchers have turned to improve the scanning accuracy with the help of various algorithmic techniques [7, 15, 16, 21, 36].

2.2 Opportunities by Programmable Switches

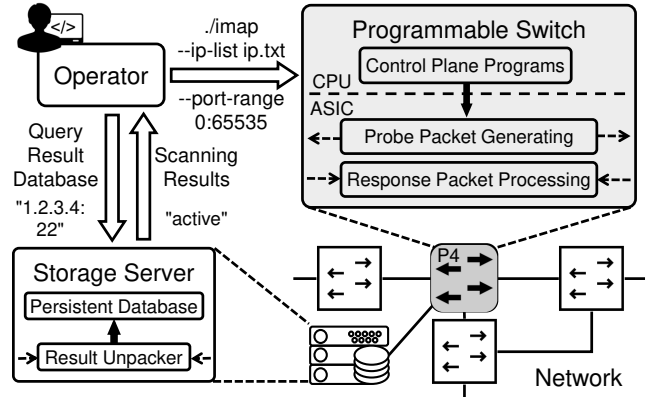
Programmable switches [8, 9] bring unprecedented opportunities to address the limitations of current network scanners.
High packet processing capability. Switching ASICs are specialized for high-speed line-rate packet processing, which can provide several orders of magnitude higher throughput than highly-optimized servers [25]. Specifically, today's latest CPU-based network scanner, Zipper ZMap [1], could only provide a scanning rate of 14.2 Mpps and a scanning throughput of 10 Gbps. In contrast, switching ASICs can easily process a few billion packets per second, which shows great potentials to be a terabit network scanner. Other hardware alternatives, such as FPGA and NPU, cannot match the performance of switching ASICs [25], thus not promising for a high-speed network scanner.
Flexibility to support scanning tasks. The most prominent characteristic of the new-generation switching ASICs is programmability. Such switching ASICs can be programmed with domain-specific languages like P4 [8], and also support stateful packet processing with user-defined logics. Besides, programs can run collaboratively between the data plane switching ASICs and the control plane switch CPUs, enabling advanced and flexible packet processing. As a result, diverse scanning tasks can be implemented in the programmable switch, which would potentially be the foundation of next-generation high-speed network scanners.
Vantage points to conduct network scanning. Existing network scanners are all located at network edges and implemented in end hosts, where the utmost scanning rate is usually constrained by the bandwidth of the end hosts. Worse yet, scanning from the end host requires an end-to-end scanning path, which inevitably results in the waste of bandwidth resources and the degradation of scanning accuracy. In contrast, switches provide a unique vantage point for network scanning tasks. Core switches usually have huge spare bandwidths (i.e., more than 50% spare bandwidth [11]), which shows substantial potentials for network scanners to tap. Moreover, scanning from a core switch is no longer plagued by the bandwidth waste or the scanning accuracy degradation resulted from


Figure 1: The workflow of IMap.

the end-to-end scanning path. This scanning vantage point is particularly valuable for high-speed network scanners.

3 IMap Overview

3.1 Deployment Scenario

Our scenario focuses on a network-centric deployment model, where the administrators of an ISP or a cloud network deploy IMap to understand their own network's security situations. IMap could also be used for Internet-wide scanning, but this should avoid causing any ethical concerns, as pointed out in ZMap [14]. Ideally, IMap should be built on a core switch, which provides both routing services and scanning functionality simultaneously. In other words, the IMap switch should first preserve the functionality of packet switching, and then behave as a high-speed network scanner when there is spare bandwidth (e.g., reports show that bandwidth occupation ratio for core switches is usually less than 50% [11]). Note that the deployment of programmable switches is not a new requirement; several ISPs/cloud networks have already replaced their legacy switches with programmable switches in their networks, which we believe is an irresistible trend in the foreseeable future [40, 43, 44]. Besides, an in-core-network scanner also raises the bar for attackers to take advantage of this powerful network scanner, as it is difficult for normal attackers to obtain such a deployment location.

3.2 Workflow and Design Requirements

IMap is designed to be a high-speed, easy-to-use network scanner, so the usage of IMap is similar to traditional network scanners, such as ZMap [14] and Masscan [33]. As shown in Figure 1, operators should first specify the scanning address spaces and scanning port ranges beforehand. Then IMap control plane programs parse these configurations and issue the parsed parameters into the IMap packet processing logic. After that, IMap data plane programs generate high-speed probe packets and process response packets accordingly. Finally, the

scanning results, i.e., the information extracted from the response packets, are written into a persistent database, such as a Redis in-memory data store [29]. In the design, implementation and deployment of IMap, we identify several different design requirements that must be satisfied to make IMap a practical high-speed network scanner, especially in terms of probing packet generation and response packet processing:

Space-complete and rate-adaptive probe packet generation(§4.1). In terms of probe packet generation, there are two key requirements in switch-based high-speed scanning. First, IMap should be able to cover the desired scanning space (i.e., |address space| × |port space|) completely, without duplications and omissions. This is a basic functional requirement for a network scanner. Second, packet switching is the first-class citizen of the switch, therefore, IMap should be able to conduct network scanning tasks without affecting normal network routing functionality. As the spare bandwidth of the network is dynamic, we need a network-aware method to generate high-speed probe packets with adaptive rate.

Correct and efficient response packet processing(§4.2). With regards to response packet processing, we also have to fulfill two requirements. First, switches are also responsible for normal packet forwarding, therefore, the input packets for the switch-based scanner have both normal packets and response packets. As a result, the scanner should be able to distinguish normal packets and response packets correctly. Second, response packets cannot be steered to servers directly, as it may saturate the bandwidth of the storage servers and overwhelm the writing capability of the database. The scanner should have an efficient response packet processing approach to reduce the server-side pressure.

4 IMap Design

4.1 Probe Packet Generation

Switch is designed to be a packet forwarding device, not a packet generation device, thus cannot generate probe packets without ground. Inspired by HyperTester [49], we also leverage the template-based packet generation mechanism to generate high-speed probe packets. As shown in Figure 2, the switch CPU first prepares a set of template packets with initialized headers, and injects them into switching ASICs. Our tests manifest 50k template packets are enough for line-rate scanning and the injection takes 15 ms, causing negligible loads on the switch CPU. After receiving these template packets, switching ASICs keep looping these packets in the switch pipeline, where each packet experiences three sequential steps: an *accelerator* to accelerate the template packets to 100 Gbps line rate, a *replicator* to replicate the template packets into several switch ports, and an *editor* to edit the headers of replicated template packets into desired probe packets.

(1) **Accelerator.** The accelerator is located at the ingress pipeline, and it keeps looping the template packets by inject-
Figure 2: Probe packet generation of IMap.

ing these packets into the *recirculate port*. The recirculate port is a special port in the switch pipeline, where the injected packets are sent back to the ingress pipeline immediately. Therefore, after injecting a set of template packets to fill the switch pipeline, we get a 100 Gbps line-rate stable packet source for the replicator.

(2) **Replicator.** The replicator is located at the traffic manager, which mainly takes the template packets from the accelerator as input and replicates these packets into a given port set with the *packet replication engine*. The packet replication engine is a hardware component in the traffic manager, which is widely supported by today's programmable switches. By configuring a set of ports for multicast from the control plane, incoming packets will be replicated and forwarded to the given port set in parallel. The original template packets from the accelerator will continue to be recirculated across the switch pipeline, to ensure line-rate stable packet source for the replicator, and the replicated template packets would go through the editor for further processing.

(3) **Editor.** The editor resides in the egress pipeline, and it is responsible to modify the replicated template packets into the desired probe packets. As long as the packet headers can be parsed by programmable switches, the headers can be set to given values, e.g., constants, or values from registers. To turn replicated template packets into probe packets, some header fields (e.g., destination IP address, destination port) need modification via the editor, while other fields (e.g., protocol type, source IP address) are inherited from the template packets which are created by the switch CPU initially.

With the steps above, we obtain continuous probe packets at line rate in multiple egress ports. Nevertheless, to be a practical high-speed network scanner, IMap should be able to generate probe packets to cover the scanning space (i.e., |address space| × |port space|) completely, and adapt the scanning rate according to the network conditions.

4.1.1 Random probe address

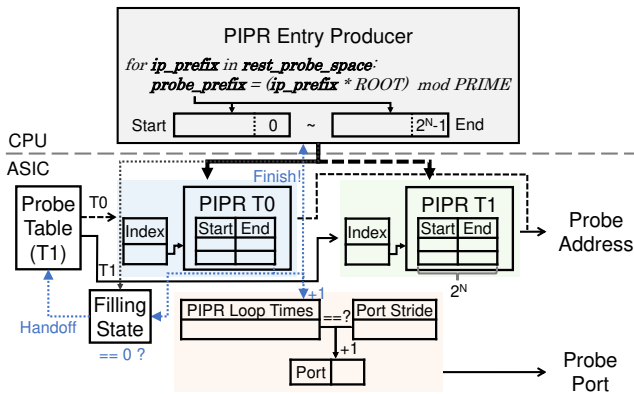
To cover the scanning address space completely, an intuitive way is to scan from the start IP address to the end IP address one by one. Nevertheless, simply probing IP addresses in numerical order would overwhelm the target networks with the scanning traffic, which may produce inconsistent probing results and incur complaints from the target networks. To avoid this, IMap should be able to scan the addresses accord-


Figure 3: Random probe address.

ing to a permutation of the address space, without duplications and omissions. However, the switching ASICs only have limited programmability and memory resources, which cannot support complex calculations or maintain massive states. The address generation approach in ZMap [14] requires calculations such as multiplication and modulo, thus is not feasible in the switching ASICs.

To address this problem, we leverage the flexibility of the switch CPU to supplement the switching ASICs to generate line-rate address-random probe packets. In the editor of the switching ASICs, we design a Probe IP Range (PIPR) table based on register arrays. In the switch CPUs, we have a PIPR Entry Producer module. Using the address generation method similar to ZMap [14], the PIPR Entry Producer module can generate a random permutation of the probe IP ranges for a given address space. After the PIPR Entry Producer module fills part of the generated probe ip ranges into the PIPR table, probe packets can iterate through the PIPR table to obtain the random destination IP addresses. As the data plane scanning is pretty fast, a PIPR table with entry size of 1 will be scanned quickly, so we store a probe ip range in each entry of the PIPR table. To implement this, our PIPR table consists of two register arrays: one is named as PIPR_Start array, which is used to store the start of the probe ip range; the other is named as PIPR_End array, to store the end of the probe ip range. Before the PIPR table, we have a PIPR_Index register, which is used to index the PIPR table. The initial value of the PIPR_Index register is set as 0 by the control plane; upon an incoming probe packet, the value of PIPR_Index increases by 1, until the size of the PIPR table; after that, the PIPR_Index is assigned as 0 again and another loop starts. For the PIPR_Start array, upon each incoming packet, the corresponding PIPR_Start register increases by 1, until the PIPR_End register. When the value of the last PIPR_Start register is equal to the value of the last PIPR_End register, the scanning for the current PIPR table is finished, and the PIPR Entry Producer module is supposed to fill a new round of probe ip ranges into the PIPR table. To send the finish signal to the control plane, we leverage the *egress to egress mirror* primitive in the switch pipeline, which can carry a predefined flag to the switch CPU

to notify the PIPR Entry Producer module.

However, conducting a new round of PIPR table filling is a time-consuming task. According to our tests on the Intel Tofino switch [23], even with the batching optimization, filling a PIPR table with size of 65,536 requires about 0.3 seconds. This indicates that, after a round of scanning, the data plane has to wait for at least 0.3 seconds to start the next round of scanning. This is unacceptable for high-speed scanning, as it compromises the scanning rate significantly. To resolve this problem, we introduce two PIPR tables and PIPR_Index registers. When one PIPR table is being scanned, the other PIPR table is being filled with the next round of probe ip ranges. To make the two PIPR tables handoff seamlessly, we design a Probe_Table register in the first stage of the egress pipeline, which is switched between 0 and 1, and controls the flow of probe packets. The switching of the Probe_Table register is triggered by the finish signal of the egress to egress mirror primitive. Definitely, to achieve continuous probe packets, there is a mathematical relation that the PIPR table size, the PIPR table filling time, and the scanning rate must satisfy. Supposing the size of the PIPR table is N, the difference between each PIPR_Start register and PIPR_End register (i.e., the size of a PIPR table entry) is L, the PIPR table filling time is T seconds, the total scanning rate R (packets per second) should satisfy that $R \leq \frac{N \times L}{T}$. However, there are still a few extreme scenarios where the actual PIPR table filling time is longer than the expected T, e.g., caused by the congestion of the switch CPU or the control channel. It means the inequality is not held and the PIPR table is being read before fully filled. To deal with such cases, we add a Filling_State register before the PIPR_Table register to indicate whether the PIPR table filling is finished. It is set to 1 when the control plane begins to fill and set to 0 when the control plane finishes the filling. The finish signal of the egress to egress mirror primitive will check whether the Filling_State register is 0 before it switches the PIPR_Table register.

Until now, the designs above only consider one port scenario, which should be extended to support a port range scenario, e.g., scanning from port 22 to port 80. Since the scanning address already has good randomness, we choose to scan the port one by one. However, updating the Port register from the control plane would bring about race conditions, as the high-speed probe packets are already looping in the switch pipeline. To address this, we design a port self-increment mechanism in the data plane. As the control plane knows in advance the number of times the scanning address space needs to loop in the PIPR table, we design a Port_Stride register in the switch pipeline, which is filled with the number of loop times by the control plane. Every time the scanning of one PIPR table finishes, the corresponding counter increases by 1, until the value of the Port_Stride register. Then, the Port register increases by 1 and the counter is set as 0 again. With all the mechanisms above, the final design of our random probe address is described in Figure 3, which achieves to generate

address-random probing packets to cover the scanning space completely, without overwhelming target networks.

4.1.2 Adaptive probe rate

To avoid affecting the normal packet routing functionality of the network, IMap desires a network-aware method to generate high-speed probe packets with adaptive rate. The "adaptive" here has two kinds of meanings. First, the control plane of the IMap switch should be aware of the nearby network conditions for further scanning rate adjustment. Furthermore, the IMap data plane should have a rate-adjusting interface, which can receive commands from the control plane to accurately adjust the scanning rate.

To be control plane aware, IMap should be able to adjust the scanning rate according to the network conditions. We formulate the scanning rate adjustment problem as follows. The scanning network can be modeled to a graph $G = (V, E)$, where V and E are sets of forwarding devices and directed links between devices. Note that link $e = (v_i, v_j)$ is directed, and (v_i, v_j) and (v_j, v_i) are different links. Each link $e \in E$ has a capacity c_e and its current load is represented with l_e. We assume there exists a monitoring system in the network, so l_e can be obtained with the port bandwidth usage of the devices connected by e periodically. IMap is deployed in $v_{IMap} \in V$ and its ports $P_{IMap} = \{p\}$ connect to the network with links $\{e_p\} \subset E$. The maximal scanning rate for port p is c_{e_p}, which is the bandwidth capacity of the link e_p. According to the routing table on v_{IMap}, we can partition the scanning space S by P_{IMap} in advance so that each port p corresponds to a routing-aware sub-scanning space $s_p \subset S$. Besides, we can estimate the extra load $d_{p,e}$ on each link e caused by full-rate probe packets of s_p. This can be done by configuring IMap to send probe packets of s_p with a specific tag on port p at low rate, then using the monitoring system to detect the load caused by the traffic with the given tag, and finally inferring $d_{p,e}$ when the scanning rate is c_{e_p} [28, 31]. Such partition and estimation should be repeated to adapt to routing dynamics when the routing tables in the scanning network change drastically. Then the scanning rate adjustment problem can be solved based on the Linear Programming (LP), as follows:

$$max \qquad \sum_{p \in P_{IMap}} \alpha_p c_{e_p} \qquad (1)$$

$$s.t. \forall e \in E: \ l_e + \sum_{p \in P_{IMap}} \alpha_p d_{p,e} \leq \beta c_e \qquad (2)$$

where $0 \leq \alpha_p \leq 1$ denotes the rate throttling parameter and $0 \leq \beta \leq 1$ denotes the maximum bandwidth occupation ratio. α_p is the output of this formulation and β is set by administrators to make the network robust for burst traffic. Equation (1) indicates that the objective is to maximize the total scanning rate on all ports. And Equation (2) states the extra load brought by IMap can not overwhelm any link in the network. Given $\{\alpha_p\}$, the control plane can determine the scanning rate

for each port. Note that our current design fits for one single Autonomous System (AS) network; for inter-AS networks, as different networks belong to different administrative domains and they are not willing to share confidential information (e.g., network topology, network utilization), it is extremely difficult to design an inter-AS network-aware rate adjustment approach accurately. IMap is mainly designed for the single-AS network scanning, and only provides a best-effort probing service for inter-AS network scanning tasks.

To make the scanning rate of IMap adjustable, we add a *throttle* in the switch pipeline, which can be adjusted from the control plane dynamically. Located in the ingress pipeline, the throttle is used to determine when the replicator could replicate the template packets. In general, the switching ASICs can provide a per-port 100 Gbps packet processing capability, thus enabling nanosecond-level (e.g., ∼6 nanoseconds for 64-byte packets) timestamp for each incoming packet. Our throttle consists of two registers in the switch pipeline. The first one is named as a timestamp register, which is used to record the timestamp of the last template packet that is successfully replicated and sent out to the editor. For every incoming template packet, we calculate the difference between the timestamp of the current packet and the timestamp recorded in the timestamp register. Upon the difference exceeds a certain threshold, we pass the template packet to the replicator and update the recorded timestamp. The second one is named as a rate register, which is used to make the aforementioned threshold configurable from the control plane. In the ingress pipeline, the rate register resides in the front of the timestamp register, and the control plane programs can fill the certain value into the rate register to achieve the rate control.

4.2 Response Packet Processing

As an in-network scanner based on the core switch, IMap is also responsible for forwarding normal packets, e.g., packets from other routers and switches in the network. IMap should be able to distinguish normal packets and response packets correctly. Meanwhile, since the throughput of response packets may be large, IMap should be able to efficiently process the response packets to avoid saturating the storage server.

4.2.1 Distinguishing normal/response packets

To distinguish response packets from normal packets, one approach is to maintain a secret state for each probe packet, and then verify whether the response packet is corresponding to the secret state accordingly. However, the switching ASICs only have limited memory resources, which cannot maintain massive secret states.

To resolve this, we design a stateless connection mechanism similar to SYN cookies [5]. Rather than maintaining states in the switching ASICs, we encode the secret state into the mutable fields of each probe packet. The fields should
Figure 4: Key update procedure of IMap.

Figure 5: Response packets aggregating in IMap.

have recognizable effects on fields of the corresponding response packets. Specifically, for TCP scanning, we choose the source port and initial sequence number; for ICMP, we use the ICMP identifier and sequence number; for UDP, we use the source port. Take TCP as a concrete example, in the egress pipeline, when IMap sends a probe packet, the editor sets *SrcPort* as $hash(Key, Proto, SrcIP, DstIP)$, and *SeqNo* as $hash(Key, Proto, SrcIP, DstIP, SrcPort, DstPort)$, where *Key* is a secret key maintained in the register of the switching ASICs. Accordingly, in the ingress pipeline, IMap has a *verifier*, which checks the *DstPort* and *AckNo* to determine whether the received packet is a valid response to the probe packet. ICMP scanning and UDP scanning work in a similar manner, except for different packet fields. After the verifier checks the validation of the response packets, similar to ZMap [14], IMap also responds a TCP RST packet to each SYN-ACK packet to close the TCP connection.

One potential issue with the method above is the security of the verifier. Currently the hash functions supported in the switching ASICs (e.g., CRC32) are relatively simple, which are not true cryptographic functions and are vulnerable to *chosen plaintext attacks* [48]. As a result, attackers may perform such attacks to restore the *Key*, and deliberately inject forged response packets to pollute the scanning results. To further enhance the security of the verifier and enable pollution-free scanning results, IMap updates the *Key* every *t* seconds. This can reduce the damage caused by compromised secret keys to a large extent: even if an attacker somehow manages to obtain the current key, such knowledge will become useless after at most *t* seconds.

However, simply updating the *Key* would result in inconsistent scanning results. For example, *Key*1 is updated to *Key*2 after IMap sends the probe packet. Soon the response packet arrives, the verifier determines this packet is invalid as the current key cannot obtain a correct validation for its packet headers. To address the inconsistency issue described above, IMap stores the last key used for a certain period of time. More specifically, IMap maintains three keys (i.e., the previous key, the current key, and the next key) at any given time. Every *t* seconds, IMap rotates a slot index from 0 to 2, and the key in $slot_i$ is used for the hash function. Each key can stay in a slot for at most 3*t* seconds; after 3*t* seconds, the key is updated by the control plane. A concrete example is shown in
Figure 4, where *T* denotes the max time interval between any probe packet and the corresponding response packet. The editor will encode the 2-bit slot index of the key into the header fields of the probe packet, and the fields should also be added in the corresponding response packet within this connection. Currently, we encode it into the source port for TCP/UDP and the identifier for ICMP. Based on the slot index, the verifier can conduct the validation correctly.

4.2.2 Aggregating response packets

To avoid saturating the storage server, IMap desires an efficient response packet processing approach. One intuitive approach is to use hash mechanisms [17, 35, 49]. However, as the key set is really large in IMap (e.g., the size of the scanning address space), even only storing 2-bit value for each key requires GB-level memory, which exceeds the memory resources of the switching ASICs (i.e., 50-100MB [35]) significantly.

To resolve this problem, instead of seeking to store all the keys/values, we adopt a response packet aggregation mechanism that is compatible with the current switching ASICs. More specially, as shown in Figure 5, IMap designs a dedicated *N*-size register array to temporarily store the scanning results. For each incoming response packet, IMap extracts its source IP, source port and state (i.e., active or inactive), and records the information in one register. When the register array is filled up, the corresponding response packet packs all the results from the register array, and goes to the storage server. To determine which register stores which result, we implement a counter in the ingress pipeline. Upon an incoming response packet, the counter increases by 1. The information extracted from the *i*-th packet will be stored in the *i*-th register. The *N*-th response packet will trigger the replication and be sent to the switch port connected with the storage server, packing and carrying all the results from the register array. Meanwhile, the counter is reset as 0 and another aggregation loop starts. With this approach, IMap achieves an *N* to 1 aggregation, reducing the pressure for the bandwidth of the storage server significantly. In the side of the storage server, we use DPDK [12], a high-performance I/O framework, to parse the result packets and extract the scanning results. Finally, the scanning results are stored in a persistent database.
Figure 6: Component layout of IMap.

5 Implementation

We implement a prototype of IMap, and make our code publicly available here [22]. Figure 6 illustrates the component layout of IMap on the data plane switching ASICs and the control plane switch CPUs.

The data plane part is implemented with ∼2K lines of P4-16 code for the Intel Tofino ASIC. In the probe packet generation module, we set the size of PIPR tables as 65536 and the size of one PIPR table entry as 256. In the response packet processing module, we utilize CRC32 as the *hash* function, allocate a 64-bit register for each *Key*, and set the size of the register array to store results temporarily as 16.

The control plane part is written in ∼3K lines of C code. It is responsible to initialize the data plane, inject template packets, receive update notifications, update entries/registers in the data plane and interact with the campus monitoring systems. In the probe packet generation module, we set β in Equation (2) as 0.8 to accommodate to traffic bursts, and solve the LP problem with the Gurobi [18] toolboxes. Since the routing tables in our campus network are pretty stable, we only estimate the extra load $d_{p,e}$ on each link by full-rate probe packets once, with the approach in §4.1.2. In the response packet processing module, to reduce the risk of suffering from chosen plaintext attacks, the control plane generates a random *Key* every t=1 second and the data plane applies Xorshift [32] as the random number generator.

Besides, the backend agent running on the storage server is implemented with DPDK, which extracts the scanning results from the aggregated response packets and writes the results into a Redis [29] database.

6 Evaluation

In this section, we evaluate IMap via testbed experiments and real-world deployments to answer the questions below:

- What is the overall effectiveness of IMap to conduct in-network scanning (§6.2)?
Figure 7: Deployment of IMap.

- Can IMap generate high-speed probe packets with random address and adaptive rate (§6.3)?

- Can IMap process response packets correctly and efficiently (§6.4)?

- How helpful is IMap in understanding our campus network's security situations (§6.5)?

6.1 Experimental Setup

IMap setup. Our testbed is composed of one 3.3 Tbp/s Intel Tofino switch (Edgecore Wedge 100BF-32X) and two Dell R730 servers. Both servers are equipped with Intel(R) Xeon(R) E5-2620 v3 CPUs and 64 GB memory, and connected to the switch via 40 GbE Intel XL710 NICs. In particular, one server runs as the storage server and the other server runs as the relay node to bridge IMap with our campus network. With the relay server, we can collect and analyze the probe packets from IMap and the response packets to IMap accurately. Working with the network administrator of our campus network, we deploy IMap to connect to one backbone switch in our campus network, as shown in Figure 7. Due to security and reliability considerations, we are not allowed to replace the backbone switch with the IMap switch. The network conditions are obtained from the monitoring systems in our campus network, according to which IMap adjusts its scanning rate correspondingly.

Baselines. We use two state-of-the-art network scanners as baselines in our experiments, i.e., Zipper ZMap [1] (Z-ZMap for short) and Masscan [33]. They are deployed on a Dell R430 server located at the network edge, which is equipped with a 10 GbE Intel 82599ES NIC to connect to our campus network. Note that 10 Gbps is the maximum capacity officially supported on the project homepage of these baseline scanners. We adopt the fastest configuration recommended in Z-ZMap [1] for baseline scanners to achieve the best scanning capability, e.g., we install "PF_RING ZC" NIC driver to support the high-speed scanning of Z-ZMap and Masscan.

Scanning Task. Since TCP SYN scanning is one of the most representative probes among single-packet probes, we use TCP SYN scanning to evaluate IMap in our experiments. The scanning target is configured to some or all ports (0∼65535)

Table 1: Scanning rate and scanning completion time.

Scanner	Scanning Rate	Time for 1000-Ports Scan[1]	Time for All-Ports Scan
IMap	55.6 Mpps	12 seconds	8 minutes
Z-ZMap	14.2 Mpps	35 seconds	33 minutes
Masscan	9.4 Mpps	51 seconds	50 minutes

Table 2: Switch resource utilization.

	Computational			Memory	
Resource Usage	Tables 42.86%	ALUs 45.84%	Gateways 18.75%	SRAM 20.83%	TCAM 0.69%

of our campus network including 6 Class B addresses, a total of up to 25 billion scanning space, which is nearly 6 times larger than Internet-wide single-port scanning space.

6.2 Overall Effectiveness

Scanning accuracy. In order to determine whether IMap can perform high-speed scanning and obtain accurate scanning results in our campus network, we examine whether the scanning rate, i.e., the rate of probe packets sent from IMap, has any effect on the hit rate, i.e., the fraction of responsive probed hosts (responding with SYN-ACK or RST in this case). We experiment by using IMap and baseline scanners to scan port 80 of our campus network and normalize the experimental results. Figure 8 shows that IMap is capable of handling scanning at up to 55 Mpps without obvious hit rate degradation. In contrast, baseline scanners such as Z-ZMap and Masscan can neither reach a high scanning rate, nor achieve a comparable hit rate (at least 1.5 times gap). These benefits are brought by the in-network deployment location and performant switch implementation. Our results also verify baseline scanners experience the decreased hit rate with the higher scanning rate due to the drop of probe/response packets [1].

Vantage point. To demonstrate the advantage of IMap in employing in-network scanning, we probe all addresses in our campus network on port 80 and measure the latency between sending a probe packet and receiving the response packet from active hosts. We also conduct the same measurement on two baseline scanners at the same time. The CDF of the results are shown in Figure 9. IMap gains much shorter round-trip response time for over 90 percent of hosts than state-of-the-art scanners. This is benefited from the fact that IMap is deployed in the core network and probe/response packets take a shorter path, 2-4 hops compared with 4-8 hops of end-to-end scanning. It also indicates the less bandwidth waste to the network and the smaller possibilities of dropping probe/response packets, which promises IMap can conduct high-speed scanning accurately and efficiently.

Fastness and scalability. To illustrate that IMap is fast and scalable in network scanning, we measure the scanning rate and scanning completion time of IMap and baseline scanners. Port 0-999 and all ports of our campus network are chosen as the scanning tasks respectively. For each scanner, we repeat both tasks for 10 trials at the midnight to minimize the impact for our campus network and report the averages in Table 1.

---

[1]It includes time to send probe packets as well as a fixed 5-second delay after all probes are sent, during which scanners wait for late response packets.

The results show IMap is able to generate 55.6 million probe packets per second (close to 40 Gbps linespeed), which is 4 times improvement compared with Z-ZMap and Masscan. Note that 40 Gbps is not the upper limit of IMap; instead, when we enable all ports of the switch, IMap can generate probe packets at terabit line rate. Currently, we cannot replace the core switch with IMap to conduct such a pressure test, which is left for our future work. Besides, Table 1 also shows IMap can complete scanning tasks much faster than the other scanners, which can help operators capture network security snapshots much more quickly.

Resource overhead. To evaluate the resource consumption of IMap, we focus on its resource usage of our test switch, which is a low-end switch with pretty limited resources. Table 2 displays the average hardware resource utilization of IMap across all stages of the switch. As we can see, even with such a low-end switch, IMap takes up less than half of computational resources, one-fifth of SRAM, and negligible TCAM, still leaving enough resources for the concurrent execution of traditional forwarding behaviors [35]. Leveraging high-end switches with more hardware resources (e.g., Edgecore Wedge 100BF-65X), the resource usage of IMap can be much lower. Besides, the resource utilization of a switch does not have any obvious effect on its forwarding performance. This is because as long as the compiled P4 program that integrates IMap and the forwarding functionality can be fitted into the switching ASICs, the switch is guaranteed to process and forward packets at terabit line rate [26, 51].

6.3 Probe Packet Generation

Random probing. To validate the randomness of probe addresses generated by IMap, we first explore the distribution of the first 1000 addresses selected by IMap and Z-ZMap when they are probing port 80 of our campus network. Considering our campus network only contains class B addresses, as shown in Figure 10, we only keep the last two octets of the IP address and map them to the x and y coordinates, respectively. Based on the results, we can see that the address randomization of IMap achieves slightly worse statistical properties than Z-ZMap because IMap employs the PIPR table, but we believe it is still good enough to avoid overwhelming the destination networks. To verify this, we analyze the pressure IMap brings to access networks. Figure 11 indicates several vital access networks in our campus network only receive thousands of probe packets per second even though the scanning rate of IMap reaches as high as 55 Mpps. Such additional packet overhead is negligible for most edge networks.
Figure 8: Hit rate vs. Scanning rate.
Figure 9: Response time of probe packets.
Figure 10: Distribution of generated probe addresses.

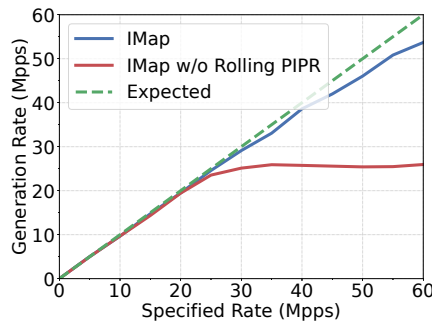

Figure 11: Network pressure for access networks.

Figure 12: Generation rate of probe packets.

Figure 13: Adaptive scanning rate.

Adaptive probing. To evaluate the adaptability of scanning rate of IMap, we first quantify the rate control accuracy of IMap by comparing the rate specified by the runtime parameter with the actual rate of probe packets sent from IMap. As shown in Figure 12, the error gradually increases with the rising of the scanning rate, but it is always limited within 5% even when the scanning rate of IMap reaches 55 Mpps. Such error mainly comes from the restricted accuracy of the packet rate in the recirculate port and can be manually corrected in the real scanning. Besides, from this figure, we can also see that rolling PIPR filling optimization (§4.1) helps IMap achieve high-speed scanning continuously. Then we investigate whether IMap can adjust its scanning rate according to network conditions. We conduct scanning on our campus network with IMap at different time, and record the rate of probe packets in Figure 13. Since the monitoring system reports the campus network conditions every 10 seconds, and the LP problem can be solved within 3 seconds for our campus network, we make IMap update the scanning rate every 10 seconds to adapt to the change of the network conditions.

6.4 Response Packet Processing

Secure verifying. The security of the response verifier is guaranteed by the dynamic key updating technique in IMap, whose efficiency is decided by the parameter t. To find a suitable value for t, we first simulate the relationship between the computing power and the time required to reverse *Key*

used by the hash function in IMap. As we can see from Figure 14, it takes about 4 seconds for high-end CPUs and more than 20 seconds for mainstream CPUs to locate the real *Key* using the stack algorithm [38]. In this case, IMap is protected from chosen plaintext attacks with t smaller than 1.3 seconds. Then we choose several different t for IMap and scan all ports of our campus network to seek how t affects probing. Figure 15 presents the number of response packets received by IMap but not pass the verifier during each scan, which occurs when the response time is beyond 3t. The results manifest that, under a common attacker, 0.3s~1.3s are all applicable choices for t in our campus network.

Response aggregating. To testify the efficiency of response packet aggregation mechanism, we configure IMap to scan the campus network at different rate, and monitor the response traffic that is sent from the switch to the storage server. Figure 16 and 17 display the packet rate and throughput of such traffic with or without aggregating response packets respectively. It can be seen that the aggregation enables a 93.8% reduction in RX rate and an 86.1% reduction in RX throughput for the storage server, which efficiently protects it from being saturated by massive response traffic.

6.5 Analysis of Scanning Results

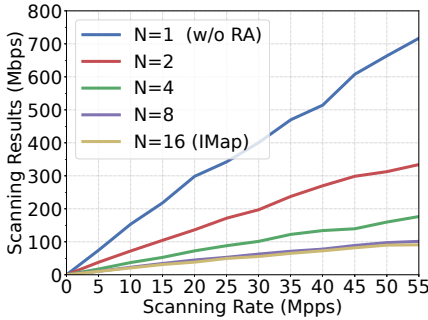
High-speed scanning of IMap has enabled the faster snapshots of the network. Therefore, we conduct an experiment where IMap continuously scans all addresses in our campus
Figure 14: Reverse time for *Key*.
Figure 15: Impact of t to probing.
Figure 16: Packet rate of scanning results.


Figure 17: Throughput of scanning results.
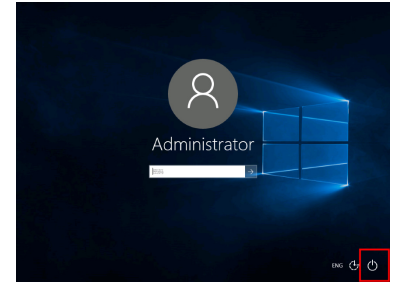
Figure 18: Activity of ports over one day.


Figure 19: RDP screenshot of an vulnerable host.

Table 3: Top 10 active TCP ports of our campus network.

Port	Service	Active Rate	Active Count	Inactive Count
8680	WeChat	1.34%	5271	12555
7680	Windows Update Delivery	1.33%	5211	12065
3389	RDP (Remote Desktop)	0.69%	2693	11659
5040	Windows Deployment Service	0.55%	2176	11709
80	HTTP	0.44%	1722	4841
135	Microsoft DCE/RPC	0.41%	1607	11081
445	Microsoft-DS	0.38%	1499	10592
139	NetBIOS Session	0.36%	1422	10559
22	SSH	0.34%	1354	4831
21	FTP	0.25%	983	10918

Table 4: Exploitability of vulnerabilities to 135 and 3389.

Port	Vulnerability	Exploitability
135	Leak the host name, OS version, timestamp	100%
	Leak all NICs and IPs	99.6%
	Leak all RPC services	98.8%
3389	Leak the host name, OS version, timestamp	81.3%
	Leak the login screen	35.4%
	Remote shutdown*	20.2%

network on all TCP ports. This experiment lasts for a week and the scanning results in the Redis database are persisted into the disk with a tag of time after each scan is over. In order to explore potential applications of IMap, based on the scanning results, we attempt to track the adoption of common protocols and discover new potential risks and security incidents in our campus network.

Protocol adoption. We first compute the average count of active and inactive hosts for each port in all time periods. Table 3 lists the top 10 open ports we observed and reveals several interesting findings. First, as the proportion of online devices in our campus network ($\sim$5%) is far lower than that of the Internet, the active rate of the port is also lower than that of the Internet. Besides, we notice IMap just receives a small number of response packets from some sensitive ports, like ports 22 and 80, and we speculate the reason is that many

systems filter such probe packets via the host firewall. Finally, we find Table 3 displays a really different sorting from that of the Internet in ZMap [14]. For example, the most active port in our campus network is 8680, which is used by WeChat, one of the most popular messaging App, and the second one is 7680, which is occupied by Windows to distribute system updates. We also observe a surprising number of open ports associated with file/device sharing over the network, such as ports 139, 445, and 5070. We attribute these differences to that more personal devices than servers are connected to our campus network. Furthermore, we then analyze the active rate variation of the top 10 ports by time over one day. As we can see in Figure 18, the active rate of some ports, e.g., 8680 and 7680, exposes an obvious diurnal pattern while that of other ports does not change significantly over time. This is because the former are usually opened by personal devices while the latter are opened by servers.

Potential risks. Among the top 10 ports, 135 (DCE/RPC) and 3389 (RDP) catches our attention because they are known for information leakage. Considering their popularity, we investi-

gate the exploitability of their vulnerabilities in our campus network. As shown in Table 4, 100% of the 135-opened hosts and more than 80% of the 3389-opened hosts are at the risk of information leakage. Moreover, the 3389-opened Windows hosts are also vulnerable to being shutdown remotely due to the misconfiguration from their users. For instance, Figure 19 is the screenshot from one of such vulnerable hosts, showing that users are allowed to perform shutdown operations on the RDP login screen. Even though the firewall of our campus network bans external access to internal hosts' sensitive ports including 135 and 3389, we believe these vulnerabilities still pose a high risk to our campus network and may be exploited by attackers. We have contacted our network administrators, and they confirmed these risks and issued a notice to remind teachers and students to check their configurations.

Botnets detection. We also implement several alarm scripts triggered when the scanning results satisfy some conditions. One of them is used to detect botnets by monitoring whether the active count of certain ports surges in the last scan. During our experiment, we did find a fast increase of 48101-opened hosts and suspected it is caused by a Mirai botnet. We reported such an issue to the network administrators immediately and they finally determined it is just an experiment on Mirai conducted by a security lab. Even we dodged a bullet, it still reflects the potential of IMap in fast revealing security incidents with high-speed scanning, which cannot be obtained in time by existing network scanners like Z-ZMap and Masscan.

7 Discussion

Scanning results v.s. deployment locations. From a network perspective, different switches have diverse network utilization, topological connection relations and access restrictions. As a result, the deployment locations of IMap affect the scanning results inevitably. Furthermore, we can also coordinate multiple switches to deploy IMap for cooperative scanning, which can achieve a higher scanning rate and hit rate. For any given network, there must be optimal distributed deployment locations in a given period of time, which can achieve the highest scanning rate and hit rate. We leave the deep exploration of optimal distributed deployment locations in a given network as our future work.

Relationship with application-layer scanners. Currently, IMap only supports single-packet scanning, including TCP SYN scans, ICMP echo request scans, and application-specific UDP scans, and does not support complex application-layer protocols, e.g., TLS handshakes, directly. However, similar to ZMap, IMap can serve as a foundation to obtain the responsive host list from the given port, e.g., port 443 for TLS protocol. Based on this list, operators can use application-layer scanners to collect advanced information, e.g., a custom certificate fetcher to retrieve TLS certificates. In a word, IMap can narrow down the scanning space for application-layer scanners significantly.

8 Related Works

Our work is highly related to the following topics.
Network scanners. Many network scanners have been developed to conduct network scanning tasks. Nmap [39] is optimized for small network segments with a wide variety of probing techniques. IRLscanner [30], ZMap [14], Masscan [33] and Zipper ZMap [1] are designed for Internet-scale scanning, mainly with a single-packet probing paradigm. IMap is very similar to ZMap and Masscan in the scanning methodology, but with different implementation targets and deployment locations, thus achieving orders of magnitude scanning capability improvement.

IPv6 scanning. Numerous research works have been devoted to improving the IPv6 scanning efficiency by optimizing the scanning space algorithmically. Entropy/IP [15] employs information entropy to segment the addresses in the hitlist and generate target addresses based on the relationship between different fragments. 6Gen [36] and Entropy-Clustering [16] extend the scope of prefix space for Entropy/IP and discover seed address fingerprint with clustering analysis. 6hit [21] adopts a reinforcement learning based target generation method to improve the probing efficiency. As a high-speed scanning system, IMap is completely orthogonal to these algorithmic works. And the scanning space generated from these algorithms can be set as the input of IMap to further improve the scanning efficiency.

Programmable switches. Recently programmable switches have been used as accelerators for various applications in networking [17, 35, 37], distributed systems [25, 26] and security [27, 34, 51], and these applications achieve far better performance with lower costs than their software counterparts running on commodity servers. The closer work to ours is HyperTester [49], which shows how to design a high-speed network tester with programmable switches. However, HyperTester neither illustrates how to generate probe packets with random address and adaptive rate, nor how to process response packets correctly and efficiently. IMap addresses these unique challenges, and thus turns a switch into a practical high-speed network scanner.

9 Conclusion

In this paper, we identify the limitations of current network scanners, and introduce IMap, a fast and scalable in-network scanner with programmable switches. We devise a set of techniques and optimizations, i.e., an address-random and rate-adaptive probe packet generation mechanism, and a correct and efficient response packet processing mechanism, to turn a switch into a practical high-speed network scanner. We implement an open-source prototype of IMap and conduct extensive evaluations to show the advantages of IMap compared with current network scanners. We hope IMap can serve as the foundation of next-generation terabit network scanners.

Abstract

The advent of switches with programmable dataplanes has enabled the rapid development of new network functionality, as well as providing a platform for acceleration of a broad range of application-level functionality. However, existing switch hardware was not designed with application acceleration in mind, and thus applications requiring operations or datatypes not used in traditional network protocols must resort to expensive workarounds. Applications involving floating point data, including distributed training for machine learning and distributed query processing, are key examples.

In this paper, we propose FPISA, a floating point representation designed to work efficiently in programmable switches. We first implement FPISA on an Intel Tofino switch, but find that it has limitations that impact throughput and accuracy. We then propose hardware changes to address these limitations based on the open-source Banzai switch architecture, and synthesize them in a 15-nm standard-cell library to demonstrate their feasibility. Finally, we use FPISA to implement accelerators for training for machine learning as an example application, and evaluate its performance on a switch implementing our changes using emulation. We find that FPISA allows distributed training to use one to three fewer CPU cores and provide up to 85.9% better throughput than SwitchML in a CPU-constrained environment.

1 Introduction

The rise of programmable network devices has transformed distributed systems design. Instead of simply moving data between servers using standard routing protocols, network devices can be programmed using domain-specific languages like P4 [8] and NPL [10] to support new network functionality, such as congestion control [100], load balancing [55, 78], and packet scheduling [103]. Commodity Ethernet switch ASICs with programmable data planes [11, 42, 92] enable the execution of these programs at many terabits per second.

While these capabilities were originally targeted at increasing network functionality, much recent work has explored their utility in accelerating application-level functionality as well. Consensus protocols [17, 65, 93], concurrency control [45, 64], vector addition [75, 97, 98], query processing operators [34, 63], and key-value stores [49, 66, 112] have all

been shown to benefit from this in-network computation [94].

However, an important class of applications has struggled to take advantage of in-network computation: those using floating point (FP) values. These occur in two broadly-deployed datacenter applications: distributed training for machine learning, and distributed data processing systems. Since programmable switches were originally optimized for networking applications, their design includes basic support only for integer operations. Applications wanting to take advantage of in-network computation with floating point values have so far worked around this in one of three ways.

The first approach is to approximate floating point operations in software running on end-hosts. This is the approach taken by SwitchML [98] as it sums gradient vectors as part of training deep neural networks. For each chunk of gradient vector elements, SwitchML executes a protocol that requires running code to convert between floating point and integer values on end hosts, as well as performing two rounds of communication. This protocol overhead is costly (see Sec. 5.3.3).

The second approach is to build a switch ASIC that includes floating point hardware. This is the approach taken by the Mellanox Quantum switch [32, 76]. Dedicating chip resources for this purpose is expensive: we show (Sec. 4.2) that adding dedicated FPU hardware takes more than $5\times$ the die area and power of integer ALUs. As a result, this is not a general-purpose approach; it has only been taken for InfiniBand switches, which have simpler routing designs and buffer requirements than Ethernet switches, and hence have spare die area. It also lacks flexibility: it is tied to specific operations on specific floating-point formats. New ML-specific numeric representations (*e.g.*, FP16 [79, 106], bfloat16 [21, 30, 53], TF32 [86], and MSFP [18]) represent an area of ongoing innovation, and adding support for a new format requires developing and manufacturing a new ASIC – an expensive and time-consuming endeavor. For example, it took four years for Mellanox to release its second version of switches with floating point support [31, 32].

A related approach is to use FPGAs or other non-switch programmable devices to implement switch-like specialized accelerators [5, 20, 27, 70]. While this yields a functional solution, the fine-grained programmability of a FPGA comes at the cost of power [111] and area: for example, Xilinx's flagship FPGA

supports ∼8 Tbps [114] of Ethernet I/O, while the Intel Tofino 2, a regular programmable switch, supports 12.8 Tbps [43].

In this paper, we argue for a different approach. We propose FPISA, which implements floating point computation as a P4 program running directly on a programmable switch. This is not straightforward: the multi-cycle nature of floating-point operations is at odds with the streaming-pipeline architecture common to P4-programmable switches today. To make it work, FPISA breaks apart each floating point value into *exponent* and *signed mantissa* and stores them separately in different pipeline stages, decomposing the corresponding sub-operations appropriately to ensure correct execution. Rather than requiring specialized floating-point hardware, FPISA repurposes network-oriented hardware elements in the switch pipeline to implement the sub-operations not supported by the switch's integer ALUs.

FPISA is a generic approach. We evaluate its feasibility on the Intel Tofino [42], a commercially-available PISA switch. We observe that constraints of the existing Tofino architecture present obstacles to a full FPISA implementation. We address this in two ways. First, we introduce an approximate FPISA design (FPISA-A) that is implementable on existing hardware, albeit with some precision and throughput limitations. Second, we propose some simple and cheap hardware modifications, based on the open-source Banzai [102] switch architecture, to enable high throughput and accuracy with FPISA. We show that such enhancements are feasible in a 15-nm standard-cell library with minimal power, area, and timing cost relative to a baseline switch chip.

Through an emulation-based study, we assess the performance benefits of our approach by implementing accelerators for the use case of distributed training for machine learning, based on the recent SwitchML [98] framework. Enhancing SwitchML with FPISA (based on both regular FP32 and ML-specific FP16) allows it to use 1-3 fewer CPU cores, giving up to an 85.9% improvement in training throughput on CPU-limited configurations, while still achieving the same training accuracy and convergence.

2 Background and Challenges

Conventional network switches are fixed-function, requiring redesign to add new features or support new protocols. However, in today's era of software-defined networking [58], rapidly evolving networking techniques and applications require new packet processing support. Programmable switches, which allow the data plane behavior to be reconfigured, provide the necessary flexibility. The RMT-based Protocol-Independent Switch Architecture (PISA) [9] has emerged as the de facto standard for programmable switch architecture.

2.1 PISA

We depict the basic protocol-independent switch architecture design in Fig. 1. The parser is a programmable state machine responsible for extracting user-specified fields of the inbound
Figure 1: Basic PISA design.

packet to per-packet metadata.[1] The ingress pipeline consists of multiple cascaded match-action units (MAUs). Each MAU has some memory (SRAM and TCAM) and ALUs. It matches fields from the packet metadata against the memory to determine the corresponding action to be taken by the ALUs. The ALUs support basic integer arithmetic and logic operations, and can be used to modify fields in the packet metadata. They can also manipulate registers, which hold state that persists across different packets.

After going through the ingress pipeline, the packet is routed to an egress port and queued by the traffic manager. Before being output, it passes through an egress pipeline that has the same structure as the ingress pipeline, and the packet header and body are reassembled by the deparser.

Programmable switches following this architecture have become commercially available on commodity switches, thanks to reconfigurable switch silicon like the Intel (Barefoot) Tofino [42] and Marvell XPliant [88]. A long line of research has showed how to use PISA switches to implement new networking protocols, offload network functions, and accelerate application-level logic [36, 94].

2.2 Floating Point Overview

We describe the flow of the most common floating point operation in applications discussed in this paper – addition – here. Note that subtraction is performed using the same process, and comparisons are typically implemented using subtraction. Regardless of specific widths, floating point values are represented with three parts: 1-bit sign, n-bit exponent, and m-bit mantissa. Typically, a floating point number is represented in normalized form: the mantissa value is in the range of $[1,2)$, *i.e.*, it begins with a leading "1" bit (which can be omitted, *i.e.*, "implied 1"). A floating point addition $C = A + B$ is performed using a five-step process: (We assume here that abs(A) ≤ abs(B).)

Extract. The three parts of A and B are extracted from the packed data. The implied "1" in the packed mantissa is expressed explicitly.

Align. The two mantissas are aligned to represent values at the same magnitude. Specifically, $mantissa_A$ (the smaller one) is right-shifted by $exponent_A - exponent_B$ bits.

Add/subtract. Now that the two mantissas are aligned, they are added or subtracted, depending on sign: $mantissa_C = mantissa_B \pm mantissa_A$.

[1]The remainder of the packet is passed through the pipeline, but cannot be matched or manipulated.

Figure 2: FPISA dataflow. Only hardware components relevant to FPISA are shown.

Renormalize. The result is scaled so that the mantissa is in the range of $[1,2)$. This is achieved by counting the leading "0" bits and left or right shifting $mantissa_C$ accordingly, then adjusting $exponent_C$ by the corresponding value.

Round and Assemble. Finally, the three parts of C are packed into a single value. The implied leading "1" of $mantissa_C$ is stripped. If more mantissa bits are available than can be represented in the packed format, the mantissa is rounded.

2.3 Challenges

Current PISA architectures do not natively support any floating point operations. This is no surprise, considering that they were designed for packet processing, and floating point support is expensive. FPUs have much larger power and area costs than integer ALUs [62, 68, 74], and the complex floating point addition procedure (Sec. 2.2) takes multiple cycles and thus introduces timing constraints.

This paper asks if we can build floating point addition operations on a commodity PISA architecture. Intuitively, it should be possible to decompose the canonical addition procedure and span it across multiple pipeline stages. However, we observe that this leads to two challenges.

First, registers are associated with specific pipeline stages, and can only be accessed from that stage. That is, each register can only be accessed once per packet, and data dependencies cannot "go backwards" to an earlier stage.[2] This poses a problem for applications, like in-network aggregation, that wish to maintain and update floating point state: it is not possible, for example, to perform the add-mantissa and renormalize steps in different pipeline stages.

Second, the available ALU operations may not be sufficient to implement all the operations necessary to implement floating point addition. For instance, on a CPU, the renormalization step might use a count-leading-zeros instruction (*e.g.*, lzcnt on x86), but we know of no PISA switch with such an instruction.

Hence, we must develop a PISA-friendly, decentralized (multi-stage) approach for floating point addition.

3 FPISA Design

How can we implement floating point operations on PISA architectures, given the challenges described above? We propose a design, FPISA, based on a new floating point

representation and a mapping of its operations to PISA pipelines, as shown in Fig. 2. In this section, we describe the basic FPISA approach in the context of an abstract PISA pipeline; Sec. 4 discusses additional challenges that occur when implementing it on existing PISA architectures.

FPISA has three key ideas:

Decoupled exponent and mantissa operations. FPISA processes operations on the exponent and (signed) mantissa components of floating point values separately, and internally stores them in separate registers. This decoupling allows them to be processed by different pipeline stages.

Delayed renormalization. Second, FPISA does not require intermediate values to be renormalized on every operation. That is, in a SwitchML-like [98] aggregation workflow, values from each client are added to an accumulator whose value is not renormalized until the final result is output. This is based on two observations about floating point renormalization. First, renormalization does not affect the correctness of floating point operations. Scaling the mantissa to place the leading "1" in its correct location is needed to produce an output value in canonical format, but a denormalized form can equally represent the same arithmetic value. Second, renormalization introduces data dependencies between the mantissa and exponent components, which makes it challenging to fit into a PISA pipeline. In particular, renormalization requires the exponent to be adjusted based on the computed mantissa, whose computation itself depends on the exponent – a circular data dependency that cannot be represented in a single pipeline traversal. To avoid this, when we read from the accumulator, we read the denormalized value, and normalize it just before sending out the final result. We do not store the normalized value back into the accumulator.

Extra bits in mantissa register. PISA architectures commonly have registers with limited bit widths: 8-, 16-, or 32-bit registers are common; on the other hand, floating point values commonly have mantissas with smaller bitwidth. We take advantage of this difference in two ways. First, we can use bits to the right of the mantissa as guard bits to aid in rounding, as is common in standard FPUs. Second, we can use bits to the left of the mantissa to avoid overflow when summing multiple values with similar exponents. When we add two values with mantissas that are all ones, the addition simply carries into the bits to the left of the mantissa.

In this section, we use IEEE 754 FP32 – which has a 1-bit

---

[2]Recirculating an entire packet is an exception. However, it is costly and bandwidth constrained.

Figure 3: FPISA's representation of FP32 in the switch.

Figure 4: Example of FPISA addition: computing the sum of 3.0 ($0b1.1 \times 2^1$) and 1.0 ($0b1 \times 2^0$). Computation is done using a 32-bit mantissa; 21 trailing zero bits are elided.

sign, 23-bit mantissa, and 8-bit exponent – as an example to demonstrate FPISA design. Other FP formats with different widths can also be supported. Fig. 2 shows FPISA's dataflow.

3.1 Representing FP in PISA

To meet the constraints of PISA, FPISA splits the storage of floating point values using the representation shown in Fig. 3. The exponent field is stored in an 8-bit-wide register array. The 23-bit mantissa is stored, right-aligned, in a 32-bit register. To unify signs and addition/subtraction operations, we store the mantissa in two's-complement signed representation.

FPISA needs more memory space to store a floating point number (*e.g.*, 8+32=40 bits for a FP32 number). However, we argue that this will not significantly reduce the efficiency of FPISA since exponent and mantissa have to be stored in different MAUs anyway. Hence, the per-MAU parallelism of floating point operations will not be affected.

3.2 Performing FP operations in PISA

By delaying renormalization until the output phase and storing exponents and mantissas separately, FPISA makes it possible to adapt the standard extract-align-add-renormalize-assemble floating point addition flow to a PISA pipeline. Fig. 2 shows the mapping of functionality to MAUs. We use a running example (Fig. 4) where an input of 1.0 is added to a register containing the value 3.0.

Extract. The first stages extract the exponent and mantissa

Match (Man$_{metadata}$)	Action (Man$_{metadata}$)
64.0.0.0/2	Right-shift 7 bits
...	...
1.0.0.0/8	Right-shift 1 bit
0.128.0.0/9	Do nothing
0.64.0.0/10	Left-shift 1 bit
...	...
0.0.0.1/32	Left-shift 23 bits
Default	Do nothing

Figure 5: LPM match-action table (MAU6) in FPISA design.

from a FP32 value in the input packet into separate metadata registers (MAU0), then add the implied "1" to the extracted mantissa field (MAU1). The decoded values are shown in Fig. 4 step (1).

Align. FPISA then compares the provided exponent value with the one stored in memory in MAU2. This updates the exponent and determines which of the two operands's mantissa must be right-shifted and by how much. The right shift itself is performed for the metadata value by MAU3, and for the memory value by MAU4 (where the mantissa register is located). In Fig. 4 step (2), 1.0 is shifted right to be expressed as 0.1×2^1

Add. In addition to shifting the mantissa of the in-memory value, MAU4 performs the mantissa addition itself. Depending on the sign bit, it either adds or subtracts the shifted mantissa value generated in the previous stage from the stored mantissa value (step (3) in Fig. 4). The resulting mantissa value replaces the previous stored mantissa.

Note that MAU4 is used both to perform the right shift of the stored mantissa and its addition. This is a necessity because the PISA architecture can only update a given register from one stage. Existing implementations may not be able to perform both operations with a single stateful ALU; we discuss how to extend them or how to work around this limitation in Sec. 4.

At the end of this process, the exponent and mantissa registers contain the result of the addition, but may not be in normalized form. For example, in step (4) of Fig. 4, the registers store the value $0b10.0 \times 2^1$. This is indeed a valid representation of the result 4.0, but is not in normalized form because the mantissa has more than one digit to the left of the binary point.

Renormalize and Assemble. FPISA delays renormalization: it does not renormalize the intermediate value stored in registers, but only when the result is to be output. Thus, multiple additions can be performed before renormalization. This offers two benefits. As mentioned before, it eliminates the need to adjust the exponent stored in memory after calculating the mantissa, avoiding a data dependency. Second, since the renormalization and assembly steps are stateless, we can place them in the (normally underutilized) egress pipeline, making more efficient use of resources.

The renormalization process itself is performed in four steps. The aggregated mantissa is first converted from its two's complement signed representation to unsigned value and sign (MAU5). FPISA then counts the number of leading zeros and

shifts the mantissa value accordingly, in order to place the leading "1" bit in the right location (MAU6).

Because no PISA switches support a count-leading-zeros operation, FPISA exploits a TCAM-based longest prefix match (LPM) table – commonly used in IP routing – to implement this function. Specifically, we construct a LPM table where each entry has an IP address with only the ith bit set, and a netmask that matches the first i bits. A match indicates that the mantissa has $i-1$ leading zeros. This is used to select the right shift action that places the leading 1 in its canonical location (bit 24 for FP32). In the example, the leading "1" is located using a match, whose bitwise representation is shown in step (5), which corresponds to the CIDR address 0.128.0.0/9; the lookup table (Fig. 5) indicates that the mantissa should be shifted right by 1. The exponent is adjusted also according to the leading zeros' count (in MAU7) – here, incremented by 1. This gives a normalized result; all that remains is to merge the sign, exponent, and lower 23 bit of the 32-bit mantissa fields (in MAU8) to put it in FP32 format.

3.3 Additional Floating Point Features and Operations

Overflow. The denormalized representation has the potential to overflow if similar values are added many times. With a signed register size of 32 bits and a mantissa size of 24 bits, there are 7 bits to the left of the mantissa available for holding overflows. This is sufficient to represent 128 additions of values with the maximum mantissa with the same exponent – an extreme case – into a single register without overflow. However, for the use cases described later in the paper, the number of operations per register is equivalent to the number of nodes in the distributed system. If overflow occurs, it can be detected and signaled to the user, who can handle it in an application-specific way.

Other FP formats. FPISA can be trivially modified to support floating point formats with different exponent and mantissa width (*e.g.* FP16, which we evaluate in Sec. 5). Likewise, block floating point formats, where multiple values share one exponent [18], can be supported by replicating the exponent register.

Rounding. For simplicity, we have described FPISA without guard digits. The combination of no guard digits and two's-complement representation provide round-toward-negative-infinity semantics. An implementation with n guard digits would simply store the mantissa shifted left n bits from what is show in Fig. 3, and would use those to perform other types of rounding after renormalization.

Reproducibility. FPISA provides reproducibility in that the same sequence of operations and values will always produce the same result. However, since FPISA performs operations in a different order than that specified in the IEEE 754 standard, the same sequence of operations and values performed on an IEEE-754-compliant CPU may yield a different result than FPISA. For the use cases we describe in this paper, IEEE 754 compliance is not a requirement.

In this paper, we have covered the two commonly-used floating point operations – addition and comparison. They are sufficient for many distributed applications. However, other more complex and costly floating point operations may be needed in the future with emerging applications (*e.g.*, congestion control [26, 54] and network security [34]). To pave the way for future PISA implementations, we briefly discuss the possibility of supporting them.

Multiplication and division. The flow of floating point multiplication is similar to that of addition in Sec. 2.2. The two major differences are (1) the two exponents are added, and (2) the two mantissas are multiplied, all as integers. For small floating point types, the mantissa multiplication can be implemented as a table lookup, without hardware modifications. For larger floating point types, integer multiplers could be added to the hardware. We implement one based on Banzai and find its overhead is acceptable: approximately the same as an adder and a boolean module w.r.t. power and area.

Floating point division has a different flow and takes more clock cycles than other basic operations [104], which means it is unsuitable to have a direct hardware implementation in programmable switches. For some use cases, division can be implemented by converting the dividend to its reciprocal at the end-host and then multiplying in the switch.

Logarithms. The core operation of a floating point logarithm is the integer logarithm of the mantissa. As prior research [3, 99, 109] shows, this can be done by a lookup table of fewer than 2000 entries with low error (<1%).

Square roots. Square roots are even more expensive and time-consuming (*e.g.*, more than 20 clock cycles) than division [69, 87, 104]. As with logarithms, we suggest a lookup-table-based approximation for this algorithm.

4 Realizing FPISA on PISA Architectures

The previous section shows how FPISA can map floating point operations to an abstract PISA architecture. Actual PISA implementations may have restrictions on MAU operations. We have implemented FPISA in P4 for the Tofino architecture. In doing so, we encountered several architectural limitations (Sec. 4.1). We show that simple architectural extensions, which can be implemented with minimal power and chip area cost, can resolve these limitations and enable a full FPISA implementation (Sec. 4.2). Alternatively, we describe an approximate approach, FPISA-A, which works around these limitations to implement a variant of FPISA for the existing Tofino architecture, albeit with tradeoffs in accuracy and resource utilization (Sec. 4.3).

4.1 Challenges

We implement FPISA addition in the P4 language [8] (~580 LoC) in a modularized manner (*i.e.*, one floating point addition per module) and compile it to the Tofino ASIC [42]. Tab. 1 shows the resource utilization of the FPISA module out of a single Tofino pipeline. Most of these resources cannot be

Table 1: FPISA resource utilization. Nine pipeline stages (out of 12 in total) are used.

Resource	Total usage	Max usage in a MAU
SRAM	1.15%	5.00%
TCAM	0.03%	4.17%
Stateful ALU	8.33%	50.00%
VLIW instruction slots	19.01%	96.88%
Input crossbar	0.09%	4.38%
Result bus	2.34%	12.50%
Hash bit	1.06%	7.93%

shared across multiple FPISA instances.

Using this implementation, we identify three limitations of the the current Tofino hardware that impact the functionality and efficiency of our FP operations.

Resource utilization of shift operations. In general, multiple FPISA modules can be deployed in parallel, sharing the same pipeline stages and overlapping with each other. For many applications, performing as many operations per packet as possible is essential to achieve high performance [98]. Unfortunately, the current Tofino architecture can only accommodate one FPISA module in its ingress pipeline, *i.e.*, only one floating point addition can be performed per packet.

After analyzing the resource utilization, we observe that the main source of overhead is performing shift operations. Specifically, FPISA needs to shift fields by a variable number of bits, in order to implement the alignment and renormalization stages. However, the Tofino ALUs can only perform shift operations with a fixed shift distance, specified as an immediate. While it is possible to emulate a variable-length shift operation with the current functionality, doing so is resource intensive. In particular, per-stage VLIW instruction utilization prevents multiple FPISA instances from sharing pipeline stages.

Lack of atomic shift-and-add. One of the pipeline stages in the abstract design (MAU4 in Fig. 2) must perform two operations: right-shifting the stored mantissa to align it with the value being added, and performing the mantissa addition. Both are stateful operations on the mantissa register, so they must be performed by the same stage's ALU. However, the Tofino's ALUs cannot perform *both* a shift and an add operation. In Sec. 4.3, we show how to work around this limitation by left-shifting the other mantissa value (from the packet metadata) instead; this allows the FPISA design to be implemented on the existing Tofino architecture, but can lead to numerical error for some workloads.

Endianness conversion. While hardly unique to FPISA, endianness conversion is a non-trivial source of overhead for FPISA applications. Network devices interpret values in network byte order (big-endian), whereas most general-purpose CPUs are little-endian. To identify and process the data correctly in the switch, endianness conversion is necessary. Traditional networking applications only need to convert byte order for headers, which are relatively small. For data-intensive in-switch applications, byte order conversion for the full payload can have high overhead. While the Tofino has functional units that can
Figure 6: Endianness conversion rate that a core can achieve and that is desired to achieve 100 Gbps line-rate.

Table 2: Stateless ALU and stateful RAW/RSAW unit areas and minimum critical-path delays in FreePDK15 library. Each of the compiler targets contains 300 instances of one of the ALUs. Power and area are evaluated at 1 GHz frequency target.

	Default ALU	FPISA ALU	Default RAW	FPISA RSAW	ALU+ FPU
Dynamic power (μW)	594.2	669.4	637.6	721.1	3590.6
Leakage power (μW)	18.6	22.8	16.8	22.1	109.8
Area (μm^2)	505.4	618.6	468.8	633.0	3837.7
Min Delay (ps)	133	135	133	151	136

do this conversion, they are not plentiful enough to convert full payloads, and thus the conversion must be done on end hosts.

To quantify the overhead, we test how rapidly a single x86 core (running at 2.3 GHz) can perform endianness conversion for different floating point formats, using DPDK's highly-optimized APIs with "O3" optimization. Fig. 6 compares the measured results with the rate needed to achieve line-rate conversion at 100 Gbps. The gap is large, particularly for lower-precision values. In particular, to reach 100 Gbps for FP16, one will need at least 11 (*i.e.*, $\lceil$desired rate/single-core rate$\rceil$) cores. Hence, the high overhead of endianness conversion will lead to either low network throughput or extra CPU or GPU utilization. In many applications, these resources are not free; for instance, in DNN training, CPUs are often busy with data preprocessing.

4.2 PISA Architectural Extensions

To avoid these problems, we propose to extend the PISA architecture with some additional support. We show that the cost of these additions is low by extending the Banzai switch architecture model [102] and demonstrating that the increase in chip area, power, and timing budget is not significant.

2-operand shift instruction. We propose to enhance the existing shifter by allowing the shift distance operand to come from metadata instead of an immediate. The proposed instruction format is `shl/shr reg.distance, reg.value`. This little-effort enhancement will significantly improve the resource efficiency of FPISA, since the shifter can directly take the table match result as operand, and two instructions (left- and right-shift) can handle all the cases.

Combined shift+add operation in one stage. If the switch can support an atomic "shift+add" operation on a register in

a single stage, we will be able to swap the mantissa, with no compromise of potential error.

In-parser hardware-based endianness conversion. Endianness conversion in the hardware is straightforward and cheap – pure combinational logic shuffling the wires. We propose a simple enhancement to the switch's parser and deparser to implement this. Specifically, we propose a P4 type annotation `@convert_endianness`, applied to entire headers, that indicates to the compiler that the parser and deparser should convert the header fields' endianness as they enter and leave the pipeline. The parser will store the corresponding result to the metadata along with a implicit tag bit adjacent to the header's valid bit. When the packet is re-assembled, the deparser will check this tag bit to determine the byte order to be emitted.

To evaluate the cost of the first two changes (the last change has near-zero cost), we modify the open-source Banzai [102] switch architecture, a PISA-like design. We modify the Verilog code for Banzai's ALU to support our proposed shift instruction and synthesize it using Synopsys Design Compiler [107] with the FreePDK 15nm FinFET standard-cell library [73], a technology node similar to that used by the Tofino. We first check whether the design can operate at 1 GHz, evaluate its power and area, and then search the minimum critical-path delay of each design to find the impact of our modifcation on timing. As the results in Tab. 2 show, an enhanced ALU may use 13.0% more power and 22.4% more area than the original ALU, while slightly increasing the minimum delay. The overhead mainly comes from connecting and storing the second operand in the shifter. We implement a stateful read-shift-add-write (RSAW) unit based on Banzai's atomic predicated read-add-write (RAW) unit. The synthesis results in Tab. 2 demonstrate that the RSAW unit uses 13.6% more power and 35.0% more area than the regular RAW unit. In terms of minimum delay, RASW is 13.5% longer than RAW, but still far from the 1ns bound at 1 GHz. Banzai provides implementations only for the functional units, not for the entire switch chip, so we are unable to directly evaluate the impact of our modifications on the full chip design. However, prior work suggests that ALUs take up only a small portion (*i.e.*, $\sim 10\%$) of the power/area budget for the entire chip [9]; from this we infer that our modifications would have negligible impact. In other words, this hardware enhancement is feasible today, and is unlikely to become a bottleneck in future hardware generations.

Finally, to compare our approach with one that includes specialized floating-point units (like the Mellanox Quantum switch [32, 76]), we synthesize an ALU that includes a hard floating point unit. The ALU+FPU column in Tab. 2 shows the result: the hard FPU is more than five times larger and more power hungry than either the default ALU or the FPISA ALU. Its high area and leakage power are costs that must be paid even when the FPU is not in use, making it challenging for a switch chip including these features to be competitive with ordinary switches in terms of efficiency, and forcing vendors to maintain separate specialized switch designs for different applications.

Conversely, the FPISA approach allows the same ALUs to support both floating-point and non-floating-point computations, enabling a single switch chip design to support both floating-point and non-floating-point workloads efficiently.

4.3 FPISA-A: FPISA on Existing Architectures

The architectural changes described above allow us to implement the full FPISA approach. We additionally want a solution that allows FPISA to run on existing Tofino switches. Achieving this requires addressing the shift-and-add limitation. (The other two, while important, impact only resource utilization.) We provide a way to approximate FPISA on existing switches by avoiding the problematic shift. This approximation, which we call FPISA-A, can lead to inaccuracies for certain patterns of inputs, though we show later that it is not a problem for some applications, including in-network aggregation for ML training workloads (Sec. 5).

Recall that the problem arises because the alignment phase may require shifting the in-memory mantissa value to align it with the value to be added, which conflicts with the need to perform addition on the same value. Note that this is not a problem when the in-memory value has a larger exponent than the in-metadata value, as only the smaller of the two is right shifted. Taking advantage of FPISA's tolerance for denormalized representations, FPISA-A *always shifts the in-metadata mantissa* rather than the in-memory value. That is, if the in-metadata value is larger than the in-memory value, we keep the exponent unchanged and left-shift the in-metadata mantissa.

This approach works, within a certain range, because FPISA internally uses wider registers for the mantissa than the basic floating point representation. For FP32, IEEE 754 uses a 23-bit mantissa, while FPISA stores it in a 32-bit register. This gives 7 bits of *headroom*, after accounting for the implicit 1-bit and the sign bit. If the value being added is *much* larger than the in-memory value, i.e., its magnitude is greater by a ratio of more than $2^7 = 128$, the headroom would be exceeded. Instead, we detect this case during the exponent comparison (MAU2 in Fig. 2) and replace the in-memory value entirely with the in-metadata one. Doing so introduces numeric error in the low-order bits.

The FPISA-A variant is supported by the current commodity Tofino switch. As described above, it can introduce numeric error (which we call "overwrite" error). However, the error only occurs when input values vary widely in magnitude, and is bounded by the difference between headroom and mantissa width. For some applications, this approximation poses little difficulty: as we demonstrate in Sec. 5, ML model training gradients generally have a relatively narrow exponent range, and the workload is in any event resilient to small inaccuracies. For others, it may be more problematic; in those cases, the architectural modifications of Sec. 4.2 will be needed.

5 Case Study: Distributed ML Training

As the model and dataset sizes have increased for ML training jobs, large-scale distributed training has become increasingly important [1, 12, 13, 21, 33, 38, 40, 41, 47, 67, 81, 91, 113]. In this paper, we focus specifically on data-parallel training, a common approach to distributed training.[3] In data-parallel training, the dataset is partitioned to multiple worker machines, each with a replica of the model. In a training iteration, each machine performs learning on its local dataset and model, generating gradient vectors. These gradient vectors are then used to update the weights that make up the model. Modern supervised ML typically employs stochastic gradient descent (SGD) [82, 83, 95] or its variants as the optimizer for iterative training. In general, the core operation of SGD is as follows:

$$weight_{(next)} = weight_{(current)} - learning\_rate \cdot gradient_{(current)},$$

where $gradient_{(current)}$ is the element-wise mean of all the local gradient vectors produced by each worker. Computing this mean requires summing (or aggregating) gradient vectors from all workers.

Prior work has observed that, as the number of workers and the size of the model grows, communication costs – specifically, the gradient aggregation procedure – increasingly become a bottleneck in distributed training [70, 71, 98, 118]. Gradient aggregation can be viewed as an "all-reduce" collective operation, a familiar concept from the HPC world – the gradient vectors are **gathered** from all worker machines, **reduced** to one vector, and **sent back** to all worker machines. It is traditionally implemented either using a parameter server [67] or a distributed reduction protocol like ring all-reduce [6, 90].

In-network aggregation has been proposed as a promising way to accelerate this collective operation, and thus distributed training [2, 27, 31, 32, 57, 61, 70, 98]. In-network aggregation performs the "reduce" (*i.e.*, sum) step of all-reduce in a network switch on the fly. This offers higher throughput and lower latency than a parameter server approach, where both the network link and host-side network stack can become bottlenecks. Compared to ring-based and other distributed all-reduce algorithms, in-network aggregation requires exchanging fewer messages, again reducing latency and network usage.

PISA switches are well suited for, and have been used for, implementing in-network aggregation without specialized hardware. A major challenge, however, is the lack of floating point support. The recent state-of-the-art in-network aggregation work, SwitchML [98], works around this by quantizing floating point values at end hosts so that the PISA switch only operates on fixed-point values. While this quantization approach has been shown not to impact accuracy [98], we show that it harms performance. In particular, quantization and format conversion requires significant CPU overhead on the worker hosts. Computing the scaling factor to use for each block also requires

---

[3]Other parallel modes, like model-parallel, may also benefit from what is discussed in this work, but we do not explore them here.

an additional network round trip. Both costs could be avoided if the switch could operate on floating point values directly.

5.1 Setup

Environments. Given the hardware constraints of the current Tofino ASIC described in Sec. 4.1, we are not able to evaluate FPISA's applicability/benefit on the distributed ML training scenario entirely on a real system. Hence, we employ different evaluation approaches for different aspects of the process.

Specifically, to measure training accuracy and the impact of error, we write a C library that simulates gradient aggregation using a faithful implementation of the FPISA-A addition algorithm and integrate this C library into PyTorch [89] to train the models. We use the apex [85] PyTorch extension to evaluate both FP32 and FP16 floating point formats. Experiments and plots with this approach are labeled with "**[SIMULATION]**".

To analyze the numerical characteristics of the trained models' gradients and measure training throughput, we use an 8-machine cluster where each node is equipped with one NVIDIA P100 16 GB GPU, two 10-core Intel Xeon E5-2630v4 2.2 GHz CPUs, and 128 GB of DRAM with data served from local SSD storage. The cluster is networked at 100 Gbps and includes one Tofino-based Wedge100BF-65X programmable switch. This cluster deploys in-network aggregation through SwitchML [98].

For gradient numerical analysis, we directly dump the gradient vectors during the training processes. In these experiments, the workers compute gradients in the FP32 floating point format. Experiments and plots with this approach are labeled with "**[TRACE]**".

For performance (speedup) evaluation, we seek to measure the performance that FPISA-A can achieve with our variable-length shift extension, which allows multiple parallel FPISA-A instances per pipeline. Because current switch hardware does not support this, we emulate FPISA-A-enabled performance by removing the end-host format conversion/quantization at the workers and performing integer computations in place of floating point computations on the switch. While this emulation setup gives nonsensical output, it provides a realistic expectation of FPISA-A performance because: (1) under Tofino, data plane programs experience a switch processing latency that depends only on the number of stages and not on the computation intensity of their specific operations, without any effect on throughput (data plane programs operate at line rate) as confirmed experimentally in previous work (e.g., [17]); (2) SwitchML uses the full set of stages on the ingress pipelines of Tofino and any potential increase of in-switch latency can be mitigated by increasing the number of aggregation slots. Note that we use this approach only for performance evaluation, and it runs on the testbed configuration described above. Experiments and plots with this approach are labeled with "**[EMULATION]**".

Benchmarks. We select seven popular state-of-the-art ML models. These models are MobileNetV2 [96], VGG19 [101],
(a) VGG (CIFAR-10). **(b)** DeepLight (Criteo 1TB). **(c)** LSTM (GBW).

Figure 7: [TRACE] Element-wise max/min ratio distribution of different models (datasets).

(a) Epoch #1. **(b)** Epoch #20. **(c)** Epoch #40.

**Figure 8:** [SIMULATION] FPISA-A's error distribution of VGG19 gradient aggregation at early, middle, and final training stages.

ResNet-50 [37], GoogleNet [108], LSTM [52], Deep-Light [22], and BERT [24]. We use all of these to evaluate training throughput, but evaluate accuracy only for the first four, since emulating FPISA-A in software is costly and those four CNNs train much faster than the other models. For CNN models, we use the CIFAR-10 dataset [59] with a learning rate of 0.1, momentum of 0.9, and weight decay of 0.0005. For other models, we use the same setting as in the SwitchML evaluation [98]. Regarding the batch size, for the accuracy experiments, we use a batch size of 16 because small batches represent a worst-case configuration from an accuracy standpoint; for the performance experiments, we use the standard batch sizes of each model listed in the MLPerf benchmark [80] and the SwitchML work [98] (*i.e.*, 2^{13} for DeepLight, 4 for BERT and 64 for others).

5.2 Characteristics of Training Gradients

The gradient aggregation workload has some common numerical characteristics that make it well suited for in-network aggregation with FPISA. In particular, FPISA can be used with existing Tofino switches using the FPISA-A approximation (Sec. 4.3); the resulting numerical error is rare and (as we demonstrate) has no impact on training accuracy.

High aggregation parallelism. In general, for each training iteration, the entire gradient vector corresponding to the training model needs to be aggregated from all worker machines. These vectors can range from several MBs to GBs. Aggregation is just vector addition; this element-wise summation provides ample parallelism.

Vector-wise distribution. As studied in INCEPTIONN [71], gradient values in each vector largely fall in the narrow range of $[-1, 1]$, and most are close to "0".

Element-wise distribution. We find that for the same element from different workers' gradient vectors at the same iteration, the relative range is also narrow. To demonstrate this, we analyze the distribution of element-wise *max/min* ratio among eight workers' gradient vectors of the training of three models and datasets (see Sec. 5.3 for detailed setup and configuration), and plot the results at the early training phase (*i.e.*, the first epoch) in Fig. 7 (we have observed similar distributions

through the mid/final phases of the training). We find that, regardless of the model and dataset, most ($\sim 83\%$) elements' *max/min* ratio is smaller than 2^7.

Precision loss/error tolerance. It is well known that small floating point error does not dramatically affect the convergence and final accuracy of ML models [15, 19, 23, 71]. This observation has motivated extensive prior research about training with low or mixed-precision floating point operations [19, 25, 46, 50, 79, 115] and compression or quantization [35, 39, 44, 71].

Thanks to these numerical characteristics, FPISA-A addition can be directly applied to the in-network aggregation scenario on current Tofino switches. As discussed in Sec. 4.3, the lack of a shift-and-add operation introduces error only when adding values that differ by more than a 2^7 ratio – which Fig. 7 shows is rare – and the workload can tolerate such error. We show later that it has no impact on model accuracy or convergence. However, as discussed in Sec. 4.1, the cost of shift operations does mean the current Tofino only accommodates one FPISA-A module per pipeline. Hence, in-network aggregation performance will benefit from the variable-length shift enhancement we propose.

5.3 Evaluation

We take a two-step approach to our evaluation. (1) We first show that FPISA-A addition will not affect the training convergence (*i.e.*, FPISA-A will not incur more training iterations), and do not consider time-wise performance. (2) We demonstrate that FPISA-A can reduce the time of each training iteration and do not consider the convergence (because it is agnostic to per-iteration time). Taken together, we conclude that FPISA-A reduces end-to-end training time.

5.3.1 FPISA-A Error Analysis

To investigate the errors to which FPISA-A addition may lead, we record the gradient vectors from eight workers during a training job. We use the C library to compare the results of FPISA-A vs. standard floating point addition for aggregating the same gradient vectors. Fig. 8 shows the (absolute) error distribution of VGG19 during different training phases.

Similar to the gradient distribution [71], the error distribu-

tion remains similar among early, middle, and final phases of training, showing FPISA-A's wide applicability. Most errors (>95%) are in the range of $[10^{-10}, 10^{-8}]$, enough to be tolerated by ML training, which we demonstrate in the next section. We further investigate the sources of the errors and find that most errors come from rounding, while the errors caused by the overwrite and left-shift mechanisms happen rarely (less than 0.9% and 0.1%, respectively, among all the addition operations in the aggregation procedure). These errors arise because, in some cases, a gradient vector's element-wise distribution is larger than FPISA-A's left-shift headroom. As a result, the smaller values may be ignored in the aggregation procedure, leading to small errors (*i.e.*, smaller than 10^{-8}).

Note that a switch implementing the full FPISA proposal, rather than just FPISA-A, would not experience these overwrite errors. Note also that no overflow occurs in this experiment, since the number of workers, and thus the number of operations per vector element, is less than the headroom available in the mantissa register.

5.3.2 FPISA-A's Impact on Training Convergence

We investigate whether FPISA-A will lead to training accuracy loss, due to the errors it imposes. We train four ML models for 40 epochs with both default and FPISA-A addition in gradient aggregation. To show FPISA-A's adaptability on different floating point formats, we train using both standard single-precision FP32 and half-precision FP16 for each model.

We plot the accuracy value during the training procedures of each model in Fig. 9 to observe FPISA-A's impact on convergence. Note that the jitters in the curves are due to the small batch size we are choosing; these are normal and do not affect the training procedure. First, we find that floating point precision does affect the training convergence. That is, in all four models, we observe slower convergence of FP16-based training compared to regular FP32-based training, as well as the final accuracy. However, FPISA-A's addition errors will not amplify such gaps. In most cases, the curve of FPISA-A addition is closely aligned with the curve of default addition. After 40 epochs, the accuracy differs by less than 0.1%. The results also demonstrate that regardless of the floating point format, FPISA-A addition will not degrade each model's accuracy. Hence, we argue that FPISA-A will not prolong the training by adding necessary epochs to converge.

5.3.3 Training Speedup with FPISA-A

In the next experiments, we evaluate the potential speedup of FPISA-A in an end-to-end training setting as well as the resulting reduction of host-based quantization overheads. SwitchML uses CPU cores at workers to scale and transform the numeric representation of gradient vectors, including both floating-point/integer conversion and byte order conversion. In contrast, FPISA-A does not have these overheads as it sends gradient vectors as floating point values directly. As described in Sec. 5.1, from an end-to-end perspective, this is the sole source of expected performance variation between SwitchML and FPISA-A. Thus, we vary the number of CPU cores and measure the throughput differences between these approaches through a microbenchmark.

In this microbenchmark, two workers reduce a 1 GB gradient vector;[4] we measure the time to complete the operation across the workers. We use 256 element packets which is the largest that SwitchML supports. After 50 warm-up invocations, we perform 250 reductions and report median and 10th-90th percentiles as the error bars.

SwitchML baselines. We use SwitchML's RDMA transport since it is more efficient that the DPDK one, and we run two versions to explore the performance implications of scaling and transforming gradient vectors on either the CPU or the GPU (where gradients are initially computed and stored). The base SwitchML version – denoted SwitchML/CPU – uses CPU cores. This benchmark assumes that the gradient vectors are already in host memory. Further, we create a new version of SwitchML – denoted SwitchML/GPU – that uses the GPU to scale and transform gradient vectors to the integer representation before copying them to pinned host memory.

Recall that SwitchML scales the gradient vectors in chunks, using a scaling factor adapted to each chunk based on a maximum exponent calculation that involves a round trip over the network. SwitchML saves the maximum exponent calculation's network overhead by overlapping the aggregation of the current chunk with the exponent calculation of the next chunk.

For SwitchML/CPU, we keep the original SwitchML logic where one chunk is equivalent to the RDMA message size. For SwitchML/GPU, we use a separate CUDA stream for each CPU core to allow parallel kernel execution. We also introduce a performance optimization where we asynchronously de-quantize aggregated messages from integer into floating point values on a separate CUDA stream thus having two CUDA streams for each CPU core. Despite these optimizations, there is an inherent overhead with launching one GPU kernel for each chunk. One potential way to avoid this could be to execute the per-chunk maximum exponent calculation as a pre-processing operation before the in-network aggregation phase; we leave this to future work.

FPISA-A approaches. We run our FPISA-A emulation in three settings. (1) FPISA-A/CPU directly adopts the RDMA implementation of SwitchML and disables host-based type conversions. SwitchML's RDMA implementation, however, involves a CPU memory copy operation into a staging area. This memory copy is not necessary in the case of FPISA-A since it can operate entirely on memory-resident native FP vectors without quantization; thus, we include a further optimization – (2) FPISA-A/CPU(Opt) – that omits this extra memory copy. Lastly, (3) FPISA-A/GPU (for comparison

---

[4]We use two workers to exclude the synchronization variability among a larger number of workers. This is to better quantify the performance differences due to the scaling and transformation overheads. We also tried 100 MB with similar results.

Figure 10: [EMULATION] Goodput of different floating point approaches on microbenchmark. The maximum theoretical goodput with framing overhead is 92 Gbps.

Figure 11: [EMULATION] End-to-end training time speedup of FPISA-A compared to the default SwitchML.

against SwitchML/GPU) includes a copy from GPU memory to pinned host memory and back.[5]

Because FPISA-A operates directly on FP vectors, we introduce two performance optimizations for FPISA-A/GPU that are not applicable to SwitchML/GPU (due to the need for chunk-based quantization). First, we use batching to amortize the cost of launching one copy operation for each chunk. Second, we asynchronously copy from GPU to host memory as a pipeline of one batch ahead of what needs to be consumed. Further, similar to the SwitchML/GPU case, we asynchronously copy back from host to GPU memory on a separate CUDA stream.

In-network aggregation goodput. Fig. 10 (left) shows that FPISA-A/CPU requires three CPU cores to achieve the 92 Gbps maximum goodput, as opposed to SwitchML/CPU, which needs four cores.[6] FPISA-A/CPU(Opt) achieves the maximum goodput with just a single core. This leaves more CPU cycles for data I/O, potentially avoiding training job stalls while waiting for input data to be preprocessed.

Figure 12: [EMULATION] SwitchML/GPU overheads at each iteration of the microbenchmark. To achieve high goodput, a message size of 256 KB or beyond is necessary. At smaller message sizes, the kernel and copy launches (solid lines) introduce a substantial latency compared to the actual kernel execution or copy latency (dashed lines).

The message size for this benchmark is 16 KB, which allows SwitchML/CPU to reach peak performance, according to the SwitchML paper [98]. Fig. 10 (middle) illustrates that FPISA-A achieves maximum goodput for a wide range of message sizes.

For the GPU variants, we find that the message/chunk size is the most important factor. Fig. 10 (right) shows that SwitchML/GPU is inefficient with message sizes below 256 KB. This is due to overheads of GPU kernel launches and copies at small message sizes (cf. Fig. 12). Increasing the number of cores does not help because CUDA implicitly synchronizes all kernel launch calls (kernel execution can be parallelized whereas kernel launches cannot). In contrast, using just a single CPU core, FPISA-A/GPU achieves the best possible performance – limited to 80 Gbps only by the bidirectional copy bandwidth of the GPU copy engines – since it can copy chunks in larger batches.[7] We expect that without

---

[5]Our testbed does not support GPU Direct, which would enable FPISA-A to use RDMA transfers out of and into GPU memory.

[6]SwitchML/CPU with 5 cores has a small performance dip due to work imbalance across cores in this particular configuration.

[7]We copy memory using 1 MB chunks as it gives the best results irrespective of the RDMA message size.

---

this bidirectional copy bandwidth limit (a constraint of our environment), FPISA-A/GPU would match the performance of FPISA-A/CPU(Opt) since it completely overlaps the memory copying with CPU and network operations.

SwitchML/GPU with a chunk size of 1 MB reaches a performance comparable (but still below) to FPISA-A/GPU. However, this requires an equally large RDMA message size whereas FPISA-A/GPU performs well even with 4 KB messages. Using large message sizes has several negative implications. First, it can introduce larger errors in SwitchML's quantization scheme since it chooses the scaling factor from a larger chunk. Second, it hurts the performance of loss recovery because the loss of a single packet entails resending the entire 1 MB message (1024 packets). Third, the performance degrades past a certain message size. This is due to limited network capacity and the reduction of pipelining, which in turn reduces the performance benefits of SwitchML's streaming aggregation. Thus, we conclude that, although performing quantization on the GPU might still be an interesting possibility for SwitchML, more work is necessary to devise an efficient implementation without increasing quantization errors and without affecting the GPU's availability for training.

Training throughput. We now confirm that FPISA-A's benefits translate into higher end-to-end training throughput. Fig. 11 reports the training throughput for seven real-world DNN benchmarks. For these experiments, we restrict the comparison to the DPDK implementation because SwitchML/RDMA is not currently integrated into the ML frameworks [98]. We focus on two scenarios – using either two or eight cores – and we measure the speedup in terms of training throughput (samples/s). We observe that FPISA-A speeds up training by up to 85.9% and 31.6% for the 2-core case and the 8-core case, respectively. Importantly, the higher speedup factors are obtained when using just two cores for communication, which frees up six cores for data I/O in this setting. The speedup is particularly significant in communication-bottlenecked models (*e.g.*, DeepLight, LSTM, BERT, VGG19), where FPISA-A is up to 85.9% faster compared to SwitchML when using the same number of cores. On the other hand, we do not see significant benefits of FPISA-A on models like GoogleNet, MobileNetV2, and ResNet-50, which are compute-bottlenecked.

By combining the accuracy results and the per-iteration end-to-end results, we can conclude that FPISA-A is able to reduce the end-to-end training time of a wide range of ML models.

6 Related Work

Accelerating distributed/networking applications with programmable switches. Recently, programmable switches have been used to accelerate a broad range of applications, including distributed key-value stores [49, 66, 112], distributed transactions [48, 64, 117], distributed storage [72, 120], packet queuing/scheduling [100, 103], network functions [56, 78], and network telemetry [7, 34, 105, 119]. While most of them

deal with packet header processing with few arithmetic operations, some perform computation on the packet's payload. SwitchML [98] and ATP [61] leverage switches for gradient aggregation but are constrained to fixed-point aggregation, which may lead to costly format conversion on the end-host and additional network round trips for exponent communication.

FPISA's approach is also applicable to other applications involving floating point operations and in-switch computing. For example, NETACCEL [63] and Cheetah [110] propose to use programmable switches to accelerate database queries by data pruning or query offloading. With the proposed architecture enhancements, FPISA can accelerate such queries with floating point as datatype. Also, other more complex floating point operations may be needed for future applications (*e.g.*, congestion control [26, 54] and network security [34]). Sec. 3.3 briefly discusses the possibility of supporting them.

Resource allocation. Much research has studied how to use in-network rate computations to support congestion control (e.g., XCP [54] and RCP [26]), queue management (e.g., CoDel [84] and AIFO [116]), or load balancing (e.g., CONGA [4]). P4QCN [29], P4-CoDel [60], and P4-ABC [77] are P4 implementations of specific protocols that require floating point support – currently unavailable in switch hardware. Sharma *et al*. proposed a library that applies approximation to work around this limitation [99]. InREC [51] and NetFC [16] proposed to use table-lookup for floating point operation emulation in programmable switches. However, they are constrained to stateless operations and need extra RAM space to store the tables. Also, few floating point operations can be done per packet, limiting parallelism. FPISA may enable new design options for in-switch resource allocation.

Extending switches' processing capability. Proposed enhancements to the RMT architecture [9] include transactions [102], disaggregated memory [14], and better stateful data plane support [28]. While many focus on improving stateful computations, none address floating point operations.

7 Conclusion

In this work, we propose FPISA, a floating point representation designed to work efficiently in programmable switches. We first implement FPISA on a commodity Intel Tofino switch, but its design limits throughput and accuracy. We then propose hardware changes based on the Banzai programmable switch architecture to avoid these limitations. We demonstrate their feasibility through synthesis using a 15-nm standard-cell library, and find minimal impact on area, power, and timing. Finally, we investigate the benefit of FPISA by implementing accelerators for distributed training application, evaluating its performance on a switch implementing our changes using emulation. We find that FPISA allows distributed training to use 25-75% fewer CPU cores and provide up to 85.9% better throughput in a CPU-constrained environment than the state-of-the-art framework.

Abstract

Network telemetry systems provide critical visibility into the state of networks. While significant progress has been made by leveraging programmable switch hardware to scale these systems to high and time-varying traffic workloads, less attention has been paid towards efficiently utilizing limited hardware resources in the face of dynamics such as the composition of traffic as well as the number and types of queries running at a given point in time. Both these dynamics have implications on resource requirements and query accuracy.

In this paper, we argue that this dynamics problem motivates reframing telemetry systems as *resource schedulers*—a significant departure from state-of-the-art. More concretely, rather than statically partition queries across hardware and software platforms, telemetry systems ought to decide on their own and at runtime *when* and for *how long* to execute the set of active queries on the data plane. To this end, we propose an efficient approximation and scheduling algorithm that exposes accuracy and latency tradeoffs with respect to query execution to reduce hardware resource usage. We evaluate our algorithm by building *DynATOS*, a hardware prototype built around a reconfigurable approach to ASIC programming. We show that our approach is more robust than state-of-the-art methods to traffic dynamics and can execute dynamic workloads comprised of multiple concurrent and sequential queries of varied complexities on a single switch while meeting per-query accuracy and latency goals.

1 Introduction

Network telemetry systems provide users (e.g., network operators, researchers) with critical insights into the state of the network by collecting information about individual packets and processing this information into high-level features in near real-time. Typically, these features are the results of user-defined queries, where a query is expressed as a sequence of high-level operations such as filter and reduce [22, 33, 43]. Generated query results drive management decisions such as deploying defensive measures in the face of an attack or updating routing to avoid congestion. A key functionality of telemetry systems is to determine how best to leverage available resources (*e.g.*, network hardware resources, such as switch ASICs or NICs; software-programmable resources, such as general-purpose CPUs) to execute a given set of queries. Due to massive traffic volumes and often stringent timing requirements, state-of-the-art telemetry systems typically make use of programmable network hardware (*e.g.*, programmable switch ASICs [2, 4, 5]) and also apply approximation techniques (*e.g.*, sketches [24, 38, 39]).

In executing user-defined queries, telemetry systems must cope with two independent and challenging sources of dynamics. First, the resources required to execute any given query depend on the underlying distributions (*i.e.*, composition) of network traffic. For example, a DDoS-detection query that counts the number of sources contacting each destination might require a counter for each destination active on the network, but the number of active destinations may vary over time [38]. The accuracy guarantees of state-of-the-art approximation techniques like sketches [39] likewise depend on traffic distributions so that if these distributions change, accuracy can no longer be guaranteed. Second, the number and type of concurrent queries submitted by a user can vary over the system's deployment. For example, an operator might need to submit followup queries to pinpoint the root cause of increased congestion. Both these sources of dynamics affect data plane resource usage implying that telemetry systems must dynamically adjust resource allocations.

Several recent efforts [38, 43] have made progress towards coping with both of these sources of dynamics individually and in isolation, but do not address challenges arising from their simultaneous presence in network telemetry systems. For example, ElasticSketch [38] presents a method for dynamically coping with changes in traffic rate and distribution. However, this effort relies on a fixed flow key which forces users to reload the switch pipeline to change queries. On the other hand, Newton [43] describes a technique to update query operations during runtime which enables users to dynamically add and remove queries as their monitoring needs

change. However, Newton does not consider the problem of adjusting resource allocations between concurrent queries as traffic composition changes. To the best of our knowledge, no recent work addresses these simultaneous sources of dynamics in an efficient switch hardware based system.

In this work, we argue that, in order to simultaneously address these sources of dynamics, *telemetry systems should be reframed as active resource schedulers for query operations*. In particular, telemetry systems must manage finite switch hardware processing resources while adapting to varying numbers and types of queries as well as varying traffic composition. To support this argument, we make the following key contributions.

Time-division approximation method. Viewing telemetry systems as online schedulers enables a new approximation technique based on time-division approximation. At a high-level, this technique observes that query operations do not need to run all the time. Instead, operations can execute during strategically placed sub-windows of the overall time window (*e.g.*, an operation could execute for 3 of 8 equal-duration sub-windows of a 5 s overall time window). This technique is grounded in cluster sampling theory which allows us to estimate error and future resource requirements.

Adaptive scheduling algorithm. We provide a closed loop adaptive scheduling algorithm which leverages time-division approximation to execute operations from many user-defined queries on a single switch ASIC. Our scheduling algorithm leverages multi-objective optimization to balance between multiple high-level goals such as prioritizing accuracy, latency, or reduced volume of reported data across queries.

Evaluation in a functional hardware prototype. To evaluate our proposed techniques, we implement *DynATOS*,[1] a telemetry operation scheduling system which leverages programmable switch hardware to answer dynamically submitted queries. Our current implementation of *DynATOS* assumes a single runtime programmable switch hardware capable of executing a restricted number of primitive operations as supported by a telemetry module found in a widely available off-the-shelf switch ASIC. We evaluate *DynATOS* on our hardware prototype and through simulation showing that (i) time-division approximation is more robust than sketches to changes in traffic dynamics while offering a similar accuracy, overhead tradeoff space, (ii) our adaptive scheduler is able to meet query accuracy and latency goals in the presence of traffic and query dynamics, and (iii) the overheads in our scheduling loop are minimal and dominated by the time required to report and process intermediate results from the switch—an overhead which can be mitigated significantly by leveraging fully programmable switch hardware.

2 Background & Motivation

2.1 Dynamic Telemetry Use Cases

Example 2.1. Consider a scenario where a telemetry system is executing the DDoS and port scanning detection tasks described in Sonata [22][2]. The first stage of these tasks finds a set of distinct elements in each time window or epoch (*e.g.*, IPv4 source, destination pairs every epoch for DDoS). Suppose traffic follows a stable pattern for several epochs with only small changes in the number of distinct elements considered by both tasks and that the telemetry system adjusts resource allocations for these two queries to achieve good accuracy. Now, suppose at some later epoch traffic changes so that a much larger number of sources are seen (either due to a natural event like a flash crowd or due to an actual DDoS attack). This larger number of sources increases the number of pairs that both queries must keep track of and either more resources will need to be allocated or accuracy will suffer.

While this example only considered a pair of queries, in realistic settings operators likely need to monitor for a wide variety of attacks simultaneously (*e.g.*, the 11 queries described in Sonata [22]). Moreover, features like number of sources or destinations commonly overlap in these types of attack detection queries so that an anomalous change in one feature may upset the resource requirements of a large number of simultaneous queries.

Example 2.2. Consider a scenario where a network operator wants to understand the root cause of TCP latency on their network. In this scenario, the operator would like to first run queries to detect when latency increases and for which hosts or subnets [18]. Once detected, the operator must submit a large number of queries to test possible causes of high latency such as re-transmissions or deep queues [33] with filter operations so that these queries only apply to the flows experiencing latency. Note that the debugging phase may require several rounds of querying with tens of simultaneous queries in each round before the root cause of the latency can be determined.

While the above examples focus on two particular tasks, the underlying concepts—of dealing with large shifts in query resource requirements caused by changes in traffic and of executing multiple queries over time in a dependent manner— are commonly encountered in network operations.

2.2 Ideal Telemetry System Requirements

In light of the above-mentioned examples, an ideal telemetry system should support the following requirements.
R1: Query diversity. Marple [33] and Sonata [22] outline how a small set of parameterized stream processing operators can enable a wide range of telemetry queries. Telemetry systems must support these kinds of generic query description interfaces, allowing filtering over packet header values,

---

[1]*DynATOS* stands for Dynamic Approximate Telemetry Operation Scheduler.

[2]The DDoS task finds destinations receiving from large numbers of distinct sources and the port scanning task finds sources sending to a large number of distinct destination ports.

Approach	R1	R2	R3	R4	R5
Static switch-based	✓				✓
Runtime-programmable	✓	✓		✓	✓
Dynamic allocation		✓	✓	✓	✓
Sketch-based	✓	✓			✓
Software-based	✓	✓	✓	✓	
DynATOS	✓	✓	✓	✓	✓

Table 1: Summary of how different approaches relate to the requirements of § 2.2.

grouping by arbitrary header fields, chaining operations, and joining the results of multiple operation chains.

R2: Approximate execution. Executing telemetry queries over the massive volumes of data flowing through networks poses heavy resource requirements. Furthermore, many telemetry queries are equally effective when computed approximately [30]. Therefore, telemetry systems should expose approximation techniques that allow trading off reduced result accuracy for lower resource requirements.

R3: Traffic dynamics. Composition of traffic changes over time, and changes may be slow, regular, and easy to predict (*e.g.*, daily cycles) or fast and hard to predict (*e.g.*, flash crowds). As discussed in Example 2.1, these changes in traffic composition lead to changes in the resource requirements for different groups of queries. Telemetry systems should robustly handle these changes without compromising query accuracy or latency [38].

R4: Query dynamics. The queries a network operator needs to run change over time. Some of these changes may be infrequent (*e.g.*, adding new queries to monitor a newly deployed service), while some of these changes may be rapid and time-sensitive (*e.g.*, adding new queries to debug a performance anomaly or to pinpoint and block a network attack). Telemetry systems should be able to handle these dynamic query arrivals and removals, realizing updates within a few milliseconds and without incurring network downtime [43].

R5: Switch hardware acceleration. Due to massive traffic volumes, stringent timing requirements, and the limited speed of a single CPU core, executing telemetry queries on CPU-based systems is prohibitively expensive [22]. As a result, telemetry systems must leverage resource-constrained hardware targets [2, 4, 5] to accelerate query execution.

2.3 State-of-the-art and their Limitations

State-of-the-art approaches each satisfy a subset of the requirements set forth above, but face limitations which hinder their ability to satisfy all requirements simultaneously.

Static switch-based approaches. Marple [33] and Sonata [22] compile traffic queries into static hardware description languages like P4 [10], demonstrating the efficiency of switch hardware in computing query results. However, these approaches fail to satisfy R4 since changing queries incurs seconds of network downtime (see [43]).

Runtime-programmable approaches. Recently, Beau-Coup [14] and Newton [43] demonstrate techniques to allow network operators to add and remove queries at runtime without incurring downtime. These efforts lay a technical foundation to address R4, but do not address the challenge of R3.

Dynamic allocation approaches. DREAM [30] and SCREAM [31] develop dynamic allocation systems for telemetry operations addressing both R3 and R4. However, these approaches do not satisfy R1 because they require query-specific accuracy estimators.

Sketch-based approaches. Many telemetry efforts address R2 by leveraging sketches [15, 16, 28, 39, 42] to gather approximate query results under the stringent operation and memory limitations faced in the data plane. However, the accuracy of sketches is tightly coupled to both the resources allocated (*e.g.*, number of hash functions or number of counters) and the underlying composition of traffic (*e.g.*, number of flows) making sketches insufficient for R3 and R4. An exception to this is ElasticSketch [38] which addresses R3 head on by dynamically adapting to varying traffic compositions. However, ElasticSketch fails to address R4 or R1 since flow keys are fixed in the sketch's implementation.

Software-based approaches. Several prior efforts leverage the capabilities of general-purpose CPUs to process traffic queries. For example, Trumpet [32] installs triggers on end hosts, OmniMon [25] and switch pointer [37] share tables between end hosts and switches in network, and SketchVisor [23] and NitroSketch [27] tune sketch-based approximation techniques for virtual switches. While these approaches work well in settings like data centers where all infrastructure is under a single administrative domain, in many settings (*e.g.*, campus or enterprise networks) it is too expensive (in terms of infrastructure cost and/or latency) to pass all packets through software and impractical to instrument end hosts.

Scheduling distributed stream processing operations. Several efforts [26, 34–36, 41] address the challenge of efficiently scheduling stream processing operations to maximize resource utilization. However, these efforts do not consider the particular types of accuracy and latency constraints encountered in scheduling telemetry operations on switch hardware.

Limitations of current hardware-based approaches. To illustrate the limitations of current static approaches [22, 33, 43] in dealing with R3 and R4, we implement the two queries mentioned in Example 2.1 and run them over a traffic excerpt from the MAWILab [17] data set which features pronounced traffic dynamics. This excerpt starts with relatively stable traffic, then suddenly, due to an actual DDoS attack or other causes (which we do not claim to identify), around the 20th 5 s time window (or *epoch*) contains a large number of sources sending regular pulses of traffic. As suggested in [22, 43], we use bloom filters tuned for the initial normal traffic to approximate the lists of distinct pairs required by the first stage of both queries.
Figure 1: Accuracy of concurrent DDoS and port scanning queries under extreme traffic dynamics.

Figure 1 shows the F1 score[3] of these approximate query implementations along with the number of tuples returned to the collector in each epoch. Before the change in number of sources, the approximation methods for both queries return highly accurate results while sending relatively few tuples. However, when the number of sources increases, the approximation accuracy of both queries suffers since the actual number of ground truth tuples (the "Baseline" trace) far exceeds the number each query was tuned for. Taking the static approach in this example shows that *when certain events of interest occur, the accuracy of multiple queries can be significantly impacted due to fixed assumptions about traffic composition.* Of course, the telemetry system initially could have tuned these queries for the anticipated number of sources, but this would lead to significant wastage of resources under normal traffic conditions and it is hard to know what to tune for without prior knowledge of the anomaly.

2.4 Design Challenges

To elucidate why prior efforts fail to meet the requirements put forth in § 2.2, we next describe the following high-level design challenges.

D1: Approximating generic query results. Efforts like Marple and Sonata develop expressive query description languages which map into data plane computation models. However, approximation of query operations is often necessary due to limited data plane resources and massive traffic volumes. It is unclear how state-of-the-art approximation methods can be leveraged to work with queries expressed in languages like Marple or Sonata. As illustrated in § 2.3, the currently proposed baseline approach of simply replacing stateful reductions in Sonata queries with sketch-based primitives requires prior knowledge of worse-case traffic situations and does not perform well under dynamic traffic scenarios.

D2: Estimating accuracy of approximations. Approximate query results must be accompanied with a sound estimate of their accuracy. This is critical for operators to understand the system's confidence in detecting a particular event or reporting a particular metric and equally critical in dynamic telemetry systems to inform the balance of resources between approximate queries. Prior efforts have made progress towards

this goal [24, 30, 31], but none anticipate accuracy estimation for current state-of-the-art generic query descriptions.

D3: Allocating finite hardware resources among variable sets of queries under traffic dynamics. Very few prior efforts address the need of a telemetry system to evaluate multiple concurrent queries on finite hardware resources. In order to handle traffic dynamics, such a system must dynamically update resource allocations based on the estimated accuracy of each query. Moreover, since it is possible that the given resources will be insufficient to meet the accuracy of all queries, such a system must enable operators to express query priorities and allocate resources with respect to these priorities.

3 *DynATOS* System Design

3.1 Overview

To tackle the above-mentioned challenges, we build *DynATOS*. At its core, *DynATOS* is composed of three main components as shown in Figure 2. Network operators submit queries to the scheduler through a high-level REST API which performs initial query validation and returns a status message along with a description of the expected query result format. The scheduler then translates queries into their primitive operations and constructs schedules for how these operations should be run on switch hardware. These schedules are then handed to a runtime component which communicates with switch hardware to execute the primitive operations and collect intermediate results. Once ready, the runtime component gathers all results and passes them back to the scheduler and operators.
Figure 2: Architecture of *DynATOS*.

3.2 Preliminaries

Scheduling horizon. Since queries can arrive at any time, we must decide when and for how far into the future resources should be scheduled. We first examine several possible approaches to this problem, then describe our approach in the next paragraph. One option is to compute the schedule each time a new query arrives and adjust all existing queries to the new schedule. While this option minimizes the time a query has to wait before it can start executing, it complicates the realization of accuracy and latency goals since the duration of the scheduling horizon (*i.e.*, until the next query arrives) is unknown when forming the schedule. Alternatively, we could compute the new schedule each time all queries in the prior

---

[3]Computed by comparing with ground truth, the F1 score is a measure of query accuracy defined as the harmonic mean of precision and recall.

schedule terminate. While this option ensures schedules can be executed exactly as planned, newly submitted queries may experience a longer delay.

We choose, instead, to make scheduling decisions at fixed windows of time which we call *epochs* (*e.g.*, every 5 s). This allows a balance between the two schemes mentioned above: queries must wait at most the duration of one epoch before executing and during an epoch queries are ensured to execute according to the schedule. In particular, we divide the scheduling epoch into N subepochs and our scheduler assigns subsets of the submitted queries to each subepoch as shown in Figure 3. Subepochs provide flexibility to schedule different queries at different times while also providing concrete resource allocation units. Queries submitted during an epoch are checked for feasibility and only considered in the following epoch. For example, in the figure, Q4 is added sometime during epoch 2, but cannot be scheduled until epoch 3. During the epoch, the scheduler collects intermediate results for each subepoch in which a query is executed and aggregates these subepoch results based on the query's aggregation operation. Once an epoch completes, results of complete queries are returned, while new and incomplete queries are considered for the next epoch. For example, in Figure 3 Q3 completes execution in the second subepoch of epoch 2 and its results are returned during the scheduler invocation before epoch 3. We further assume that each query executes over traffic in a single epoch and telemetry tasks requiring longer measurement durations than our scheduling epoch can simply re-submit queries.
Figure 3: Example of scheduling 4 queries with $N = 3$ subepochs per epoch.

3.3 Key Ideas

We develop a novel approximation method to address the challenge of gathering approximate results for generic queries (D1). In particular, our method leverages cluster sampling theory to estimate the results of the first aggregation operator in multistage queries. For example, in the DDoS query we only approximate computation of the distinct source, destination pairs list and execute all subsequent operations exactly. The intuition behind this is that each operator in a telemetry query tends to reduce the volume of data passed to the next operator. Therefore, reducing the resource requirements and volume of data emitted from the first aggregation reduces the load on all subsequent operators.

§ 4 describes how our approximation method can provide

sound estimates of result accuracy without prior assumptions about traffic characteristics (addressing D2). Note that the accuracy estimates used in many sketch methods are dependent on traffic characteristics (which can be estimated by auxiliary queries or offline analysis) [39]. Our method, on the other hand, uses cluster sampling to estimate result accuracy based on observations from a single epoch independently of traffic characteristics. Moreover, by leveraging observations of feature variance in prior epochs, we can predict resource requirements for a desired accuracy level in future epochs. This feedback loop allows our system to dynamically adjust per-query allocations as traffic distributions change.

To address D3, we integrate our approximation technique in a scheduler that determines how a number of concurrent queries should be executed on a single switch hardware, balancing resources between queries to satisfy accuracy and latency goals set by operators. As described in § 5, our scheduler uses a novel multi-objective optimization formulation of the problem of when to run which queries given query priorities and resource constraints. This formulation allows the scheduler to balance between the goals of multiple concurrent queries, sometimes allocating less than the exact number of subepochs when queries have lower priority and resources are scarce (*e.g.*, due to a large number of concurrent queries).

Finally, we develop a runtime system leveraging these ideas to efficiently execute schedules on switch hardware, gather intermediate results, apply factors to correct for sampling, and return results to network operators in a high-level format. Operators can then decide to execute new queries in the subsequent epoch, or to re-execute the current queries based on these results.

3.4 Limitations and Assumptions

Monitoring problems addressed by *DynATOS*. The types of traffic features which can be monitored by queries in *DynATOS* are subject to the following assumptions.

- Feature values do not fluctuate excessively over measurement durations of one or two seconds.
- The monitoring task can be implemented using features gathered at a single point in the network.
- Features are constructed from packet header fields and/or other switch-parsable regions of the packet.
- Features can be computed using atomic filter, map, and reduce operations.

Under these assumptions monitoring tasks like detecting microbursts [13], identifying global icebergs [19], and detecting patterns in TCP payloads [9] cannot be efficiently executed using *DynATOS*. However, as evidenced by the body of prior efforts with similar assumptions (*e.g.*, [22, 30, 33]) and the concrete examples discussed in § 2.1, *DynATOS* can still be used for a wide variety of useful tasks.

Switch hardware model. In the following, we assume a restricted runtime programmable switch hardware model. In this model, switch hardware is able to execute a fixed set

of Sonata [22] operators, in particular, a filter operator followed by a reduce operator. However, similar to Newton [43], our switch hardware allows arbitrary parameterization of these operators *at runtime*. For example, switch hardware could execute the filter and reduce commands required by the Sonata TCP new connections queries for a period of time, then quickly (*e.g.*, within a few milliseconds) be re-programmed to execute the filter and reduce commands required by the Sonata DDoS query. We note that our scheduling methods are independent of this particular switch hardware model and could readily be applied to more fully programmable ASICs [5,10].

Network-wide scheduling. Ultimately, operators need to query traffic across different logical or physical domains of their network. This implies that telemetry systems should collect information from a distributed set of switches (or other monitoring points) and provide a global view of network traffic. In this work, we consider only a single monitoring point (*e.g.*, a critical border switch) and leave the challenges of distributed scheduling of telemetry operations to future work. Nonetheless, a single switch deployment on a enterprise or data center border switch can still be highly effective in executing the types of queries considered.

4   Time-Division Approximation in *DynATOS*

Accuracy tradeoff. Given fixed scheduling epochs, we can trade off accuracy for reduced resource requirements by sampling a subset of the subepochs in which to execute a particular query. We leverage cluster sampling theory [29] to expose this tradeoff while maintaining accuracy goals. Cluster sampling is a good fit for situations like dynamically scheduled query operations where the cost of sampling large groups of the population (*i.e.*, subepochs) is significantly lower than the cost of sampling individual population members (*i.e.*, packets) [29]. In particular, we assume sending the aggregate results (computed in switch hardware) of each sampled subepoch to software is cheaper than sending individual sampled packets to software.

Consider the case where a particular query executes in n of the N total subepochs and let $t_{i,j}$ be the query's result in the i-th subepoch of the j-th epoch, n_j be the number of subepochs in which the query executed in the j-th epoch, E be the total number of epochs in which the query is executed, and $s_{t_j}^2$ be the sample variance of the $t_{i,j}$'s in the j-th epoch. We use the unbiased estimator,[4]

$$\hat{t}_E = \frac{1}{E}\sum_{j=1}^{E}\hat{t}_j = \frac{1}{E}\sum_{j=1}^{E}\frac{N}{n_j}\sum_{i\in S_j}t_{i,j} \qquad (1)$$

which has standard error

$$SE(\hat{t}_E) = \frac{N}{E}\sqrt{\sum_{j=1}^{E}\left(1-\frac{n_j}{N}\right)\frac{s_{t_j}^2}{n_j}} \qquad (2)$$

---

[4]See § A for a full discussion of the derivation of these equations from cluster sampling theory.

to estimate query results and determine when accuracy goals have been fulfilled. We rearrange Equation 2 as

$$n^{acc} = \frac{s_{t_E}^2 N^2}{E^2\sigma^2 - \left(\sum_{j=1}^{E-1}\mathrm{Var}\left(\hat{t}_j\right)\right) + Ns_{t_E}^2} \qquad (3)$$

to estimate the number of subepochs in which a query should execute in the E-th epoch to fulfill a given standard error target σ assuming the query has already executed in the previous $E-1$ epochs without fulfilling σ. Note that if $\sigma = 0$, then $n^{acc} = N$ and the query will be executed in all of the subepochs in its first epoch. As σ increases, n^{acc} decreases freeing more of the subepochs for other queries.

Latency tradeoff. In addition to the accuracy tradeoff discussed above, we can tradeoff result latency for reduced resource requirements by executing a query's operations across several epochs. The key observation enabling this tradeoff is that by spreading the sampled subepochs over several epochs, the query can reduce its per-epoch requirements while still attaining its accuracy goal. Operators leverage this tradeoff by specifying larger latency goals on queries that do not require fast returns.

Suppose a particular query has a latency goal of $\tilde{E}$ epochs. We need to estimate the number of subepochs in which the query should be allocated n^{lat} in the e-th epoch with $1 \le e \le \tilde{E}$. First, we break the sum in Equation 2 into *past* ($1 \le j < e$) and *future* ($e < j \le \tilde{E}$) components. We then have,

$$n^{lat} = \frac{s_{t_E}^2 N^2}{\tilde{E}^2\sigma^2 - N^2\left(past + future\right) + Ns_{t_E}^2} \qquad (4)$$

While the *past* component can be calculated directly using observations from prior epochs, the *future* component must be estimated based on the number of subepochs the query expects to receive in future epochs. Operators can tune this expected number of subepochs based on current and expected query workloads.

Correcting distinct operators. While the previous sections discuss foundations for making sound approximations of packet/byte counts, many useful queries also involve identifying and counting distinct elements. We leverage the Chao estimator without replacement[5] to correct estimates of a common class of distinct count queries such as the DDoS query considered in § 2.1. Similar to the cluster sampling estimators described in this section, the Chao estimator can be used to obtain point and standard error estimates based only on the observed sample.

5   Scheduling in *DynATOS*

5.1   Optimization Formulation

We cast the task of generating query schedules as an optimization problem and adapt well-known techniques to generate

---

[5]See § A.3 for details.

schedules through this casting. While this section details our casting of the problem, § 5.2 describes the challenges inherent in applying optimization techniques in a real-time setting such as ours.

We apply our optimization formulation every epoch to determine which queries should execute in each of the N subepochs as shown in Algorithm 1. First, in line 2 we use the DISENTANGLE method of Yuan et al. [40] to break the submitted queries Q into disjoint traffic slices K and save the mapping between queries and slices in $s_{i,k}$. Line 3 then computes the minimum number of stateful update operations required by the reduce operators of all queries in each particular slice. These steps are necessary given our single-stage switch hardware model (§ 3.4). Next, lines 4 through 6 compute estimates of the memory and subepoch requirements of each query. Finally line 7 creates and solves the optimization problem described below. If a feasible solution cannot be found, line 9 falls back to a heuristic scheduling method described in § 5.2.

Algorithm 1 Method for determining subepoch schedule

1: **procedure** GET-SCHEDULE(Q, u, SE)
2:     $K, s \leftarrow$ DISENTANGLE(Q)
3:     $U \leftarrow$ COMBINE-UPDATES(u, K, s)
4:     $m \leftarrow$ ESTIMATE-MEMORY
5:     $n^{acc} \leftarrow$ EQUATION 3(σ)
6:     $n^{lat} \leftarrow$ EQUATION 4(σ, E)
7:     $d \leftarrow$ SOLVE-OPTIMIZATION
8:     **if** d is infeasible **then**
9:         $d \leftarrow$ GET-HEURISTIC-SCHEDULE
10:     **end if**
11: **end procedure**

Inputs. Table 2 shows the particular inputs and outputs of this optimization problem. Of the input variables, t_k, u_i, $s_{i,k}$, T, A, and M are known exactly based on submitted query requirements and available switch resources, while m_i, n_i^{acc}, and n_i^{lat} must be estimated based on observation of past epochs. Our current implementation uses EWMA to estimate m_i and $s_{t_E}^2$ (as required by n_i^{acc} and n_i^{lat}) independently for all update operation types. We leave exploration of more sophisticated estimation approaches to future work. Scheduling decisions are encoded in the $d_{i,j}$ indicator variables which determine which queries should execute in each subepoch. We do not consider the division of switch memory between queries since memory is dynamically allocated during the aggregation operation (see § 3.4).

Constraints. We impose the constraints shown in Table 3 to satisfy two high-level requirements: (i) respecting switch resource limits (C1, C2, C3) and (ii) forcing minimal progress in each query and ensuring variance estimates are well-defined (C4). Note that C2 captures the fact that if two queries rely on the same update operation, they can be merged to use a single ALU. In the case that the estimated quantity m_i turns out to

Variable	Description
Q	index set of queries ready for execution
SE	index set of subepochs
K	index set of all disjoint traffic slices
U_k	index set of all update operations in slice k
t_k	number of TCAM entries required by slice k
u_i	index of update operation required by query i
$s_{i,k}$	indicator that query i requires slice k
m_i	memory required in each subepoch by query i
n_i^{acc}	number of subepochs required for accuracy goal for query i (§ 4)
n_i^{lat}	number of subepochs required for latency goal for query i (§ A.2)
T	total available TCAM entries
A	total number of available switch ALUs
M	total available SRAM counters
$d_{i,j}$	indicator that query i executes in subepoch j

Table 2: Variables used in optimization formulation of scheduling problem. The sole outputs $d_{i,j}$ determine the schedule for the next epoch.

C1: $\forall j \in SE, \ \sum_{k \in K} t_k \mathbf{I} \left[\bigvee_{i \in Q} d_{i,j} s_{i,k} = 1 \right] \leq T$

C2: $\forall j \in SE, \ k \in K, \ \sum_{u \in U_k} \mathbf{I} \left[\bigvee_{i \in Q} d_{i,j} s_{i,k} \mathbf{I}[u_i = u] = 1 \right] \leq A$

C3: $\forall j \in SE, \ \sum_{i \in Q} d_{i,j} m_i \leq M$

C4: $\forall i \in Q, \ \sum_{j \in SE} d_{i,j} \geq 2$

O1: $\text{minimize} \sum_{i \in Q} \left| \left(\sum_{j \in SE} d_{i,j} \right) - n_i^{acc} \right|$

O2: $\text{minimize} \sum_{i \in Q} \left| \left(\sum_{j \in SE} d_{i,j} \right) - n_i^{lat} \right|$

O3: $\text{minimize} \sum_{i \in Q, j \in SE} d_{i,j} m_i$

Table 4: Objective functions considered in the multi-objective formulation.

be violated by traffic conditions in the subsequent epoch, we simply drop new aggregation groups once the available switch memory is totally consumed.

Objectives. In computing the schedule of each epoch, we consider the objective functions listed in Table 4. O1 seeks to satisfy accuracy goals by minimizing the distance to the value of n^{acc} computed in Equation 3, O2 seeks to satisfy latency goals by minimizing the distance to the value of n^{lat} computed in Equation 4, and O3 seeks to limit the maximum volume of data that needs to be returned from the switch in a single subepoch. We expose the Pareto front of these objective functions using linear scalarization which allows operators to express the importance of each objective by submitting weights and is computationally efficient.

5.2 Challenges of Online Optimization

Unlike prior work (*e.g.*, [22]), the inputs to our optimization problem are dependent on task dynamics (*e.g.*, the set Q can vary each epoch) and traffic dynamics (*e.g.*, the suggested n_i^{acc} could increase in response to increased traffic variability). Hence, we must solve the optimization problem independently in each epoch. However, invoking an optimization solver in an online scheduling method is fraught with challenges. First, certain combinations of inputs and constraints can lead to infeasible problems where it is impossible to satisfy all constraints. Second, since integer programming is a well known NP-complete problem, finding an optimal solution can take exponential time in the worst case. In what follows, we describe several precautions that we take in the design of our scheduler to ensure these challenges do not adversely affect the performance of the telemetry system.

Dealing with infeasible queries. Our first strategy to deal with infeasible optimization problems is to require that all submitted queries can be executed on the given switch resources in the absence of other queries. In particular, if a query requires more than T TCAM entries, A ALUs, or M counters, the scheduler must reject that query outright, since it will not be able to execute on the given switch hardware. This ensures that our scheduler can always make progress on the current pool of submitted queries by selecting a single query and allocating the full switch resources for all subepochs. We note that a query partition scheme similar to Sonata [22] could be added to our system to handle this case more elegantly, but leave this to future work.

Dealing with slow optimizations. To deal with the potentially exponential time that could be required to converge to an optimal solution, we limit the duration of time spent in the optimization algorithm to an acceptable fraction of total epoch time. This method, known as early stopping, is a well-known technique to gather feasible, good, if not fully optimal solutions. When the optimization process stops due to this time limit, the current solution must still be checked for feasibility and only allowed to execute if it is, in fact, feasible.

Fail-safe. In cases where the optimization problem is either proven infeasible or times out before converging, we fall back to a simple heuristic "fail-safe" mode of scheduling. We also deny all new query submissions when in fail-safe mode to notify the operator that the system is currently saturated and to prevent the accumulation of a large backlog which could cause the optimization problem to remain infeasible in future epochs. Our simple heuristic fail-safe scheduling scheme greedily selects the query closest to its deadline and allocates this query fully to switch resources. To increase progress in fail-safe mode, we also add other queries that use the same or a subset of the selected query's traffic slices until either the memory or ALU limit is reached. Since queries scheduled in this mode execute for each subepoch, $n_j/N = 0$ for that epoch ensuring progress towards accuracy targets, though some queries may suffer increased latency.

Another approach to dealing with situations where a feasible schedule cannot be found is to send slices of traffic to the collector and compute query results in software. In this approach queries running during fail-safe mode could still meet tight latency goals at the expense of increased load on the collector. Depending on the nature of situation triggering fail-safe mode, this could impose infeasible processing loads on the collector or lead to excessive congestion between switch and collector. In future work, we plan to investigate solutions to this problem including combinations of heuristic scheduling and moving query operations to software.

6 Evaluation

In this section, we describe our evaluation of *DynATOS* and demonstrate the following key results.

- The time-division approximation technique in *DynATOS* is more robust than state-of-the-art in the face of traffic dynamics and offers comparable performance to state-of-the-art sketch-based approximate techniques (§ 6.2).
- The scheduling method in *DynATOS* handles dynamic query workloads with up to one query every second and leverages specific accuracy and latency goals to reduce per-query resource usage (§ 6.3).
- Latency overheads in *DynATOS* are minimal and dependent on the load on the collector and the number of queries which must be updated in switch hardware (§ 6.4).

6.1 Experimental Setup

Setting. We evaluate *DynATOS* on a BCM 56470 series [8] System Verification Kit (SVK) switch running BroadScan [1] which implements the telemetry operations described in § 3.4. Our version of BroadScan has $A = 8$ parallel ALU operators, and a flow table with $M \approx 9$MB of memory. A software agent on the switch's CPU manages reconfiguration of hardware in response to requests from the collector. Our collector and scheduling software runs on a server with an Intel Xeon Gold 5218 CPU at 2.3Ghz and 383GB memory. This server is equipped with a 40Gb Mellanox MT27700-family network card connected directly to the SVK's data plane. A separate 10Gb Intel X550T network card on the same server connects to the SVK's management interface to manage updates to hardware configuration as schedules execute.

Traces. Unless otherwise stated, we replay a trace from the MAWILab traffic data set (Sept. 1st, 2019) [17] using `tcpreplay` [7]. We selected this trace as a baseline because some of its features are static while others are more dynamic.

Default parameters. We use five-second scheduling epochs to allow sufficient measurement duration without incurring excessive delay of results which must wait for epoch boundaries. We divide epochs into $N = 8$ subepochs so that the schedule has sufficient options for arranging queries without making subepochs too short to generate useful samples. We set objective weights to balance between priorities and suppose queries will get all future subepochs when evaluating

Equation 4. Queries are submitted with realistic values of σ based on baseline measurements of their variances in the trace. We set $\alpha = 1/2$ in the EWMA estimation described in § 5.1. Bars show median and error bars show 5th and 95th percentiles over all epochs of the trace.

Query workloads. We use *DynATOS* to implement four of the telemetry queries originally introduced by Sonata [22] and used in several recent efforts. Our hardware model handles a fixed sequence of filter and reduction operations so we implement the remaining query operations in software. This scenario is equivalent to Sonata with a limited number of switch hardware stages. We report the accuracy of approximate implementations of these queries as F1 score (the harmonic mean of precision and recall) by comparing against ground truth computed offline. In addition to static queries, we generate dynamic query workloads based on random processes to evaluate *DynATOS* (see § 6.3). To the best of our knowledge, there is no comparable publicly-available dynamic query workload benchmark. Our workloads are publicly released at [6] to support validation of our results and to facilitate benchmarking of similar systems in the future.

Implementation. We implement the *DynATOS* scheduler in ~14k lines of C and C++. Following ProgME [40], we use BDDs to represent query filter conditions in our implementation of the DISENTANGLE algorithm (§ 5.1). We use the open source CBC implementation [3] to solve the optimization problems described in § 5.1. Our implementation also defers some result processing operations to the time spent waiting for results from switch hardware to improve efficiency.

Comparisons. We compare *DynATOS* with ElasticSketch [38], Newton [43], and SketchLearn [24]. We modified the implementations of both ElasticSketch and SketchLearn to support the filter and reduce operations required by several of the Sonata [22] queries. Though we were unable to locate a publicly available implementation of Newton, we implemented its sketch-based approach to approximating Sonata's primitive operators. In particular, we use count-min sketch [15] to approximate the `reduce` operator and a bloom filter [20] to approximate the `distinct` operator.

6.2 Performance of Time-Division Approximation

Robustness in the face of traffic dynamics. To address the question of what happens when traffic composition changes significantly we consider an excerpt from the MAWILab dataset taken on Nov. 14th, 2015. As shown in Figure 4, this excerpt features nominally static traffic followed by a dramatic surge in the number of sources around 100 seconds into the trace.

To understand how different methods handle this change in traffic dynamics, we first tune each method's parameters to achieve high accuracy (F1 > 0.9) on the first 100 seconds of the excerpt, then run the method with these parameters over the entire excerpt. Since it is possible that this anomaly
Figure 4: Number of distinct sources and destinations in excerpt from MAWILab data on Nov. 14th, 2015.

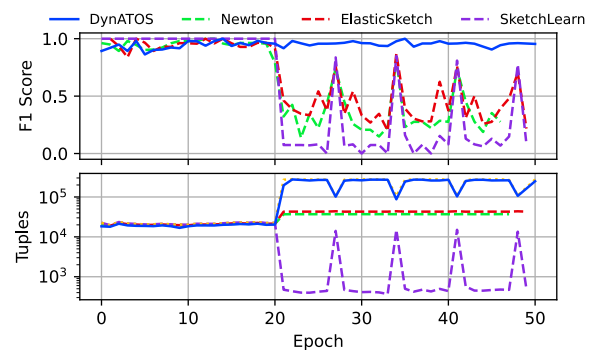
was cause by some form of DDoS attack, we run the DDoS query in this scenario to locate the victim of the attack. This is intended to reflect a realistic situation where a method was deployed and tuned for a particular traffic composition, which then changes. In real deployments, such changes could be caused by attacks or performance anomalies and represent the moments when data collected from a telemetry system is most critical.


Figure 5: Performance of different methods on the 2015 MAWILab excerpt shown in Figure 4.

Figure 5 shows the F1 score and number of tuples returned to the collector in each epoch over the trace excerpt. All methods achieve high accuracy for the first 20 epochs, but then when the number of sources increases after the 20th epoch, they diverge significantly. First, we note that *DynATOS* is able to maintain high accuracy where other methods suffer by dynamically increasing the load on the collector. This is a result of the natural robustness of our non-parametric sampling method: when the underlying traffic composition changes, those changes are reflected in each sampled subepoch causing the volume of data reported for each subepoch to increase to ensure steady accuracy.

The sketch-based methods in ElasticSketch and Newton, on the other hand, are limited by the static table sizes configured for the first 20 epochs: once the traffic composition changes, these tables become saturated and excessive hash collisions lead to F1 scores below 0.5. We confirm that the average number of hash collisions per epoch jumps by $2\times$ when the traffic distribution changes in epoch 21. We note that these sketch-based methods also offer no easy way to estimate the accuracy of returned results, so while an operator may become suspicious due to the slight increase in load on the collector, they would have no way to verify that the accuracy of these methods is compromised.

Sketchlearn differs from other methods in that it reconstructs flow keys based on data stored in a multi-level sketch.

Sketchlearn guarantees only that it will be able to extract all flows that make up more than $1/c$ of the total traffic where c is the fixed number of columns in the sketch. We confirm that in this trace, the increased number of sources is caused by a large number of small flows (one to two packets). As such, the threshold to be extracted increases, but none of the added flows are able to meet it and so SketchLearn is unable to extract existing as well as new flows with high enough confidence. SketchLearn does associate accuracy estimates with these results so an operator could be notified of this situation, but would have to reload their switch's pipeline with a larger value of c in order to achieve acceptable accuracy.

Overall accuracy-load tradeoff. As in previous efforts [22], we consider the volume of data returned from switch hardware to the collector (*i.e.*, load on the collector) as a critical resource. Each approximation method can reduce this load while reducing accuracy of query results, leading to a performance curve in accuracy vs. load space. To empirically estimate this curve, we determine several different parameterizations of each method, execute the method with each parameterization over all epochs of the trace, then compute the accuracy and load on collector in each epoch. For some queries the sketch-based methods must export their full sketches to the collector so we report load in terms of both tuples (the number of records or events) and bytes (the total size of data). We use the median of each value over all epochs to estimate the empirical performance curves.

(a) DDoS

(b) TCP New Connections

(c) Port Scan

(d) Super Spreader
Figure 6: Accuracy vs. overhead curves.

Figure 6 shows performance curves for four different queries with two plots for each query showing overhead as tuples and bytes on the *y*-axis. Here we use the baseline

MAWILab trace so these results represent a mostly static traffic scenario. Note that the lower right-hand corner of these plots is ideal with maximal accuracy and minimal load. We observe that *DynATOS*' novel approximation method (§ 4) performs as well as, if not better than other methods. The sketch-based method proposed by Newton achieves slightly better performance in terms of total data volume on the DDoS and Super Spreader queries because it only sends flow keys from the first distinct operator whereas other methods also return a counter. SketchLearn requires relatively large multi-level sketches to be exported each epoch in order to achieve comparable accuracy on these queries despite it's lower tuple counts. In the case of TCP new connections, we were unable to run a large enough sketch to reach the accuracy range shown here for other methods. We observe that for the TCP new connections query Newton's count-min sketch is highly sensitive to sketch size. For example, adding a single additional counter moves the F1 score across the entire range shown in the plot. *DynATOS*, on the other hand, achieves comparable if not higher performance and offers a wider range of load savings.

6.3 Performance of Scheduling Algorithm

Dynamic query workload. Real telemetry system deployments must deal with dynamics in the number and types of queries submitted to the network over time. Since, to the best of our knowledge, no representative dynamic query workloads are available, we synthesize such workloads based on the following scheme. First, we generate a series of base queries with random aggregation keys and granularities and arrival times based on a Poisson process with rate λ. We suppose these base queries are submitted by a human operator or automated process which then submits followup queries based on base query results. In particular, when each base query terminates, we submit between 0 and 3 followup queries with the same aggregation as the base query, but filters added to select a single aggregation group from the base query's results. For example, if a base query with aggregation key source IP address at 8 bit granularity returned results for 0.0.0.0/8, 10.0.0.0/8, and 192.0.0.0/8, we might submit followup queries to monitor just 10.0.0.0/8 and 192.0.0.0/8. To provide contrasting accuracy and latency goals, base queries are submitted with looser accuracy goals (σ = 100) and latency goals randomly chosen within a range of 1 to 5 epochs, while followup queries are submitted with tighter accuracy goals (σ = 50) and a latency goal of 1 epoch.

Figure 7 shows the evolution of the number of queries submitted by one of our dynamic query workloads (top plot) and traces of different operating metrics (lower three plots). In this workload, the maximum number of queries is submitted in epoch 8 which leads to an infeasible schedule since too many TCAM entries are required to keep track of all filter groups of followup queries. This causes our scheduler to enter fail-safe mode for two epochs to dispatch with the excess queries. Note
Figure 7: Example time-series of a dynamic query workload (3/5 queries per second).

Figure 8: Performance of *DynATOS* on dynamic query workloads.

(a) ALU-seconds   (b) counter-seconds

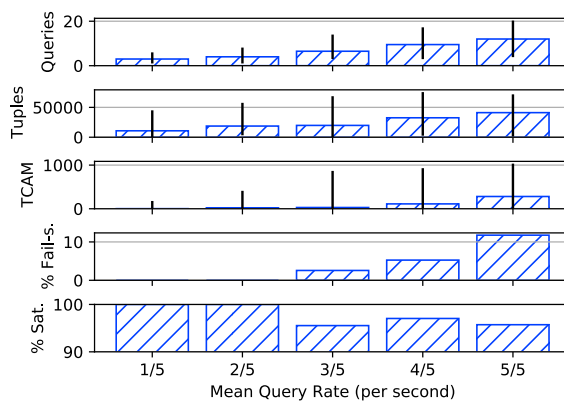
Figure 9: Evaluation of median resource usages for selected accuracy (y-axis) and latency (x-axis) targets for a single query. Lighter colors indicate lower resource usages.

that the heuristic algorithm currently used to select queries in fail-safe mode only selects a few queries based on fully disjoint traffic slices leading to reduction of load on collector and TCAM utilization. Under the software-based fail-safe mode mentioned in § 5.2, the load on collector would continue increasing here while TCAM utilization would drop.

To understand how *DynATOS* scales with the rate of dynamic query workloads, we generate a set of five workloads with different base query arrival rates. Figure 8 shows how these different workload intensities affect the performance of *DynATOS* in terms of queries served (Queries), tuples emitted to the collector (Tuples), TCAM entries used (TCAM), epochs spent in fail-safe mode (% Fail-s.), and the percentage of satisfied queries (% Sat.) all per-epoch. We count the number of queries satisfied as the total number of queries that received valid results during the workload run. Note that some queries submitted when the scheduler is in fail-safe mode are denied at submission time allowing an operator to re-submit these queries later. In these experiments we observe that all successfully submitted queries receive results within their target accuracy and latency goals.

We observe that, as expected, the number of queries serviced, load on collector, and number of TCAM entries required all scale linearly with the base query rate. As also expected, the number of queries satisfied decreases as more epochs are spent in fail-safe mode. We observe that the main contributor to infeasible scheduling problems in this scenario is the number of TCAM entries required to satisfy followup queries' filter conditions. We plan to investigate integration of more efficient TCAM allocation algorithms in future work to address this bottleneck.

Relaxation of accuracy & latency goals. Next, we evaluate how our approximation and scheduling method is able to reduce the per-query resource requirements in response to relaxed accuracy and latency goals. We execute the TCP new connections query with varying accuracy and latency goals and measure resource usage over 10 epochs at each setting. Here we report ALU-seconds and counter-seconds which combine both the number of ALUs (or counters) used by the query and the duration for which these resources were used.

Figure 9 show the resulting resource usages as both accuracy and latency goals vary in the form of heatmaps. These


results demonstrate that both accuracy and latency goals can help *DynATOS* leverage our time-division approximation method to reduce resource requirements.

6.4 Scheduling loop overheads

Closed-loop systems like *DynATOS* must quickly gather results and update switch hardware configurations between each subepoch in order to avoid missing potentially critical traffic. We define the inter-epoch latency as the total time spent not waiting for results from switch hardware. In other words, the inter-epoch latency is the total time taken by our system to gather results, reconfigure hardware operations, and decide which operations to execute in the next epoch. We observe two distinct factors that contribute to the inter-epoch latency: the load on the collector and the number of queries installed in switch hardware.

Latency vs. load on collector. The first factor contributing to inter-epoch latency is the volume of data that must be returned and processed after each subepoch. To isolate this effect, we generate synthetic traffic consisting of a certain number of sources each sending a steady stream of packets controlled by a Poisson process. We then run a query that returns a single record for each source so that by varying the number of sources in the traffic, we directly control the number of records returned and hence the load on collector.

Figure 10 shows the distribution of total latency for two different loads. We observe that the median inter-epoch la-

(a) 10 Records   (b) 10^5 Records
Figure 10: Distribution of inter-epoch latency in our testbed system for different loads on the collector.

tency in both cases is less than 130 ms, but that with higher load the tail latencies grow to over a second. This is likely due to that fact that the collector code must allocate larger memory blocks to process the increased number of tuples returned from the switch. We leave a full investigation of the performance of our software collector to future work.
Figure 11: Software overheads as function of tuples exported.

We further investigate how the different components of our query scheduler impact this overall inter-epoch latency by instrumenting the scheduler. Figure 11 shows the latency break down as a function of the number of records processed for three key components: the time to generate a schedule for the epoch (Schedule Gen.), the time spent processing intermediate results at the end of the epoch (Proc. Results), and the time spent sending results back to the query-submitting process (Result Delivery). The results demonstrate that the main variable software latency is the time to process results which scales nearly linearly with the number of records. A more significant bottleneck is imposed by the result delivery time due to the use of a simple REST protocol which requires new TCP connections and data marshaling via JSON. We leave exploration of more efficient IPC mechanisms for this interface to future work.

Latency vs. number of queries. The second main factor contributing to inter-epoch latency is the time required to install and remove query operations on switch hardware. This factor is influenced primarily by the amount of state which must be written into hardware memory which is a function of the number of queries to be installed or removed. We generate synthetic workloads containing different numbers of disjoint queries based again on the TCP new connections query and instrument our switch agent to measure the time taken by writes into hardware memory.

Figure 12 shows the time taken by the hardware writes to add and remove operations (Add Hw. and Remove Hw.) as well as the total time taken by the switch agent (Add Tot. and Remove Tot.) which includes the time to deserialize and validate configurations sent from the collector. These results show that up to 100 queries can be added or removed on our
Figure 12: Hardware overheads as function of number of queries.

prototype in $\sim$10 ms (comparable to latencies reported in prior efforts [30, 43]). We also observe that the deserialization and validation conducted by the switch agent imposes minimal overhead. Finally, the total contribution of switch hardware to the overall inter-epoch latency is dominated by operation removal. This is because when removing operations, the switch agent must also reset the entire flow table used by these operations so as to avoid future operations anomalously reporting leftover results.

7   Conclusion and Future Work

Current approaches to telemetry system design struggle to efficiently satisfy dynamism in query workloads and traffic workload composition. By reframing telemetry systems as resource schedulers, in this work, we propose an efficient approximation and scheduling algorithm that exposes accuracy and latency tradeoffs with respect to query execution to reduce hardware resource usage. We evaluate our algorithm by building *DynATOS* and show that our approach is more robust than state-of-the-art methods to traffic dynamics and dynamic query workloads.

While we investigate the common sources of dynamics, both a *horizontal scheduling problem* (*i.e.*, how to design a scheduler to deal with those dynamics for multiple switch hardware stages or multiple distributed switches) and a *vertical scheduling problem* (*i.e.*, incorporation of computing resources, such as stream processing clusters and GPUs—both locally and at remote cloud data centers—into the pool of resources schedulable for telemetry tasks) remain. This opens up a wider question of *where*, not just *when* and *for how long*, telemetry queries should be executed. We plan to investigate this question as part of future work.

A Appendix: Application of Cluster Sampling

In this section, we discuss details of key equations enabling our scheduling approach's accuracy and latency tradeoffs. To maintain a self-contained discussion, some content is repeated from § 4.

A.1 Trading Off Accuracy

Given fixed scheduling epochs, we can trade off accuracy for reduced resource requirements by sampling a subset of the subepochs in which to execute a particular query. We leverage cluster sampling theory [29] to expose this tradeoff while maintaining accuracy goals. To simplify our discussion, we first consider the case where a query is executed in a single epoch and then expand to the case where a query is executed across multiple epochs.

Single Epoch Case. Consider the case where a particular query executes in n of the N total subepochs. Our goal is to estimate the value that would have resulted from running the query in all subepochs based only on these n subepoch results. First, we note that each subepoch defines a cluster of packets that traverse the switch during that subepoch. Next, since each query executes over every packet of the subepochs in which it is scheduled, we note that the subepoch results represent a sample of n of the N total subepoch clusters. To ensure that each subepoch has an equal probability of being sampled by a particular query, we shuffle subepochs prior to execution. Cluster sampling theory [29] then lets us estimate the results of these queries over the entire N subepochs as well as the error of this estimator based on the variance between the observed subepochs. For example, we can estimate a query that maintains a sum by

$$\hat{t} = \frac{N}{n} \sum_{i \in S} t_i$$

which has standard error

$$SE(\hat{t}) = N \sqrt{\left(1 - \frac{n}{N}\right) \frac{s_t^2}{n}}$$

where S is the index set of which subepochs have been sampled, t_i is the query's result in the i-th subepoch, and s_t^2 is the sample variance of the t_i's. Clearly, executing a query for fewer subepochs leads to greater sampling error while executing a query in each subepoch leads to zero sampling

error. This equation also shows that, if n is set to a fixed ratio of N, error grows as a function of N so we do not expect to increase accuracy by dividing epochs into larger numbers of subepochs. Corresponding theory and equations exist for other update operations such as averages and extreme values.

Multiple Epoch Case. Due to changing traffic distributions or large query workloads, a query may not be able to fulfil its accuracy goal in a single epoch and the scheduler must form results based on the estimates from multiple epochs. Considering again the sum example, let $t_{i,j}$ be the query's result in the i-th subepoch of the j-th epoch, n_j be the number of subepochs in which the query executed in the j-th epoch, and E be the total number of epochs in which the query is executed. By the self-weighting property of $\hat{t}$, we can take a simple mean of the $\hat{t}_j$'s to get an unbiased estimator of the query's result over the E epochs,

$$\hat{t}_E = \frac{1}{E} \sum_{j=1}^{E} \hat{t}_j = \frac{1}{E} \sum_{j=1}^{E} \frac{N}{n_j} \sum_{i \in S_j} t_{i,j} \tag{5}$$

which has standard error

$$SE(\hat{t}_E) = \frac{N}{E} \sqrt{\sum_{j=1}^{E} \left(1 - \frac{n_j}{N}\right) \frac{s_{t_j}^2}{n_j}} \tag{6}$$

because subepochs are chosen independently in each epoch (*i.e.*, the sampled index sets S_j, which are the only random variables in this formulation, are independent).

Application to Scheduling. Our system uses the point estimates provided by Equation 5 to calculate estimated query results. We also utilize Equation 6 for two purposes: (i) determining when accuracy goals have been fulfilled and (ii) estimating the number of subepochs in which the scheduler must execute particular queries. Since the first item can be evaluated with a simple threshold check, the rest of this section explains the second item. We assume that each query executes a single update operation (*e.g.*, a sum) in its reduction and note that multiple operations could be expressed in multiple queries.

Note that for a given standard error target ($SE(\hat{t}_E) = \sigma$) we can rearrange Equation 6 to solve for the number of subepochs that must be sampled in the E-th epoch as follows,

$$n^{acc} = \frac{s_{t_E}^2 N^2}{E^2 \sigma^2 - \left(\sum_{j=1}^{E-1} \text{Var}(\hat{t}_j)\right) + N s_{t_E}^2} \tag{7}$$

Given a query's target standard error σ, observed values of $s_{t_j}^2$ and n_j from prior epochs, and an estimate of $s_{t_E}^2$ (based on the $s_{t_j}^2$'s), we can use Equation 7 to determine a lower bound on the number of subepoch in which a query should execute. Note that if $\sigma = 0$, then $n^{acc} = N$ and the query will be executed in all of the subepochs in its first epoch. As σ

increases, n^{acc} decreases freeing more of the subepochs for other queries. For example, Figure A.1a shows the result of evaluating Eq. 7 for the first epoch of a query, indicating that if the accepted standard error is large enough, the scheduler only needs to execute the query in a single subepoch.

Limitations. We note that Equation 7 can become unstable when the accuracy goal σ cannot be obtained in a single epoch given the results of prior epochs. This condition results when $E^2\sigma^2 + Ns_{t_E}^2 \leq \sum_{j=1}^{E-1} \text{Var}(\hat{t}_j)$ causing the value of n^{acc} to be negative or undefined. Moreover, when n^{acc} is negative, its magnitude has the wrong sense with respect to σ: smaller (tighter) values of σ reduce the magnitude of n^{acc}. Rather than dropping the query, we make a maximum allocation choice ($n^{acc} = N$) and retain the query for future epochs until its accuracy target is met. So long as $\text{Var}(\hat{t}_j) < \sigma^2$ for enough of those future epochs, n^{acc} will eventually stabilize.
(a) Increasing σ reduces n^{acc} in the first epoch.

(b) n^{lat} increases as deadline $E = 6$ approaches.

Figure A.1: Numeric evaluations of Eqs. 7 and 8 assuming fixed variance $s_t^2 = 8$, $N = 5$, and queries get $3/5^{th}$ of the subepochs.

A.2 Trading Off Latency

In addition to the accuracy tradeoff discussed above, we can tradeoff result latency for reduced resource requirements by executing a query's operations across several epochs. The key observation enabling this tradeoff is that by spreading the sampled subepochs over several epochs, the query can reduce its per-epoch requirements while still attaining its accuracy goal. Operators leverage this tradeoff by specifying larger latency goals on queries which do not require fast returns. We then adapt Equation 6 to estimate how many subepochs should be executed in the current epoch based on both past and anticipated future results.

Accounting for Past and Future Results. Under the latency tradeoff, we approach the problem of determining how many subepochs to execute from the perspective of the point in the future when the query completes. At this point Equation 5 will be used to estimate the query's result and Equation 6 must satisfy the query's accuracy goal. Moreover, assuming we are satisfying the query's latency goal, E is equal to the target number of epochs.

Now we consider the task of estimating the number of subepochs to execute during some epoch e before the query's final epoch E. Note that the sum in Equation 6 can be split

around epoch e into a past component

$$past = \sum_{j=1}^{e-1} \left(1 - \frac{n_j}{N}\right) \frac{s_{t_j}^2}{n_j}$$

and a future component

$$future = \sum_{j=e+1}^{E} \left(1 - \frac{n_j}{N}\right) \frac{s_{t_j}^2}{n_j}.$$

We can then directly adapt Equation 7 to provide the required number of subepoch in epoch e accounting for both past and future components as

$$n^{lat} = \frac{s_{t_E}^2 N^2}{E^2\sigma^2 - N^2(past + future) + Ns_{t_E}^2} \quad (8)$$

Figure A.1b shows the result of evaluating Equation 8 in each epoch leading up to a query's target latency of $e = 6$ assuming that the operation gets $3/5^{th}$ of the number of subepochs requested in each epoch. Since in this case, the query is not given its full requested number of subepochs, the target n^{lat} increases dynamically to meet the deadline. This indicates that Equation 8 can dynamically drive scheduling decisions even when its results are not taken literally in each epoch (as may be the case when multiple queries compete for resources).

Limitations. Equation 8 faces the same issues as Equation 7 in that it may still be infeasible to satisfy σ given past results and the anticipated gains of future results. In such cases we again take $n_j = N$ and count on gaining sufficient resources in future epochs to satisfy the accuracy goal. To understand the dynamics of this decision, Figure A.2 shows the relation between target and actual number of epochs for a number of accuracy goals. We assume here that queries anticipate getting $3/5^{th}$ of the subepochs, actually receive $3/5^{th}$ of what they ask for, and all other settings are as in Figure A.1. As can be seen when the accuracy target is too tight (*e.g.*, $\sigma = 6$) executing in less than a certain number of epochs ($e = 5$) is infeasible and the query's latency goal cannot be met.
Figure A.2: Relation between target number of epochs and the actual required number of epochs.

A.3 Correcting Distinct Operators

Many useful queries also involve identifying and counting distinct elements. We consider the particularly prominent

query structure where the results of a distinct operator are fed through a reduce operator with a slightly coarser granularity key. For example the DDoS query considered in § 2.1 contains two main stateful operators: (i) finding distinct source, destination pairs and (ii) reducing with destination as the key to count the number of unique sources contacting each destination. The key problem is that, while the methods above provide sound estimators for packet and byte counts, they do not correct for elements which may have been entirely missed in the distinct operator due to sampling. Such errors lead to a downward bias on distinct counts based on sampling which could cause key events like DDoS attacks to go unnoticed. To correct for this source of error, we leverage the Chao estimator without replacement when performing reductions after distinct operators impacted by sampling. Chao estimators [11, 12] are commonly used by "species richness" studies in the biological sciences to solve a related type of distinct count problem [21]

This estimator is given by

$$\hat{S}_{Chao1,wor} = S_{obs} + \frac{f_1^2}{\frac{n}{n-1}2f_2 + \frac{q}{1-q}f_1} \tag{9}$$

where S_{obs} is the number of elements observed in the sample, f_1 is the number of elements observed only once, f_2 is the number of elements observed only twice, n is the total number of elements in the sample, and q is the sampling rate. To use this estimator, we modify distinct operators executed in the data plane to additionally count the number of packets observed for each distinct element (essentially transforming them into normal count reduction operators). After gathering results, we can then easily compute the inputs required by Equation 9. Note that the variance of $\hat{S}_{Cha1,wor}$ can also be easily obtained from the same information as shown in the original description of this estimator [12], providing network operators with approximate accuracy of these results as well.

HeteroSketch: Coordinating Network-wide Monitoring in Heterogeneous and Dynamic Networks

Anup Agarwal

Boston University

Srinivasan Seshan
Carnegie Mellon University

Abstract

Network monitoring and measurement have always been critical components of network management. Recent developments in sketch-based monitoring techniques and the deployment opportunities arising from the increasing programmability of network elements (e.g., programmable switches, Smart-NICs, and software switches) have made the possibility of accurate, detailed, network-wide telemetry tantalizingly within reach. However, the wide heterogeneity of the programmable hardware and dynamic changes in both resources available and resources needed for monitoring over time make existing approaches to network-wide monitoring impractical.

We present HeteroSketch, a framework that consists of two main components: (1) a profiling tool that automatically quantifies the capabilities of arbitrary hardware by predicting their performance for sketching algorithms, and (2) an optimization framework that decides placement of measurement tasks and resource allocation for devices to meet monitoring goals while considering heterogeneous device capabilities. HeteroSketch enables optimized deployments for large networks (> 40,000 nodes) using a novel clustering approach and enables prompt responses to network topology, traffic, query, and resource dynamics. Our evaluation shows that HeteroSketch reduces resource overheads by $20-60\%$ compared to prior art, while maintaining monitoring performance, coverage, and accuracy.

1 Introduction

The ability to monitor network traffic in-situ and at-large-scale is a critical enabler for many networked management applications, including traffic engineering, load balancing, attack and anomaly detection, provisioning, and congestion control/fairness [1–7]. However, network-wide monitoring has proven to be challenging due to limitations on what measurements can be made and where these measurements can be taken. Recent developments in sketch-based monitoring and network programmability have made significant progress in eliminating these limitations and have made it possible to consider practical network-wide monitoring designs.

Sketch-based monitoring designs [8–13] demonstrate that sketches offer provable accuracy guarantees on a wide spectrum of metrics of interest using a small amount of memory and that independent sketch instances monitoring different parts of the network can be merged to obtain network-wide aggregated results. As a result, sketch-based monitoring has emerged as a promising alternative to traditional sampling-based monitoring tools (e.g., NetFlow [14] and sFlow [15]). The growing popularity of programmable network elements, such as programmable switches [16, 17], SmartNICs [18, 19], and software-switches [20, 21], have made it possible to deploy these sketch-based designs throughout a network – enabling highly-effective network-wide monitoring capabilities.

Despite significant recent progress [10–13, 22], we argue that deploying sketch-based monitoring in a network-wide setting remains impractical. The reason behind this is that existing network-wide solutions [11, 22, 23] assume an abstract network model without properly considering the *heterogeneity* and *dynamics* in the network. First, with growing types of programmable devices whose hardware architectures are dramatically different (e.g., ASIC, CPU, FPGA), it remains unclear how to deploy sketches among heterogeneous computation and memory hierarchies for optimized resource efficiency. Second, since monitoring capabilities share the same infrastructure with other network services [24–26] and monitoring requirements vary over time, the available and required resources for monitoring can change dynamically. We require an agile solution that can incorporate device heterogeneity and quickly adjust to network dynamics for best possible monitoring performance.

In this paper, we present **HeteroSketch**, a network-wide flow monitoring framework that coordinates sketch-based measurement to determine task placement and resource allocation for a network of heterogeneous devices. HeteroSketch has two main components: (1) a device characterization tool that automates quantified reasoning about the performance and resource usage of sketches on arbitrary de-

vice architectures and (2) an optimization framework that computes the placement of measurement tasks while considering available heterogeneous device resources and monitoring goals including forwarding performance, resource efficiency, monitoring accuracy, and flow coverage.

When designing our device characterization tool, we need to deal with a broad spectrum of programmable architectures such as CPU [20, 21], FPGA [19, 27], ASIC [16], and multi-core system-on-chip (SoC) [18]. Given the difficulty in accurately predicting the performance of arbitrary code under diverse workloads and hardware architectures [28, 29], we scope our efforts to sketches to create a practical solution. Our design is inspired by the observation that many sketches perform similar computations. We analyze the key operations of sketches and find that the performance of a sketch depends heavily on primitive operations – hash computations, counter updates, and random memory lookups. With that in mind, we then characterize these operations on current (and possibly new) hardware using automated micro-benchmarks, and leverage these measurements to express the performance and resource usage of a sketch. As evaluated in §7.1, our profiler accurately predicts sketch performance on programmable hardware with less than 6% mean relative error.

With precise performance profiles as input, HeteroSketch must address the tightly coupled monitoring goals, traffic demands, forwarding performance, sketch configurations, and resource usage, and the tradeoffs between them. Task placement and resource allocation requires a carefully crafted optimizer to incorporate the cost/benefit of different deployment options. We formulate a Mixed-Integer Program (MIP) to optimize resource efficiency while preserving forwarding performance, monitoring accuracy, and flow coverage.

Given the complexity introduced due to heterogeneous devices (non-convexity) and network scale, even a state-of-the-art solver [30] takes hours to solve the MIP, leading to stale solutions in face of network dynamics. We develop a clustering technique based on observed structures in network topologies and traffic patterns to partition the optimization into independent sub-problems. This allows HeteroSketch to scale to today's data center networks having tens of thousands of devices and respond to dynamics within a few seconds to a few minutes while maintaining near optimal allocations.

We implement HeteroSketch by porting state-of-the-art sketch implementations [8, 9, 11, 13] into representative programmable devices (Barefoot Tofino [16], Netronome Agilio SmartNIC [18], Xilinx FPGA NIC [27], and Open vSwitch (OVS) [20]) and encode the optimization in the Gurobi [30] solver. Our evaluation with more than 40,000 nodes demonstrates that our heterogeneity-aware optimization can achieve 20 − 60% better resource efficiency (e.g., 50k CPU cores instead of 70k CPU cores) compared to prior solutions with the same performance, accuracy, and coverage while responding to network dynamics in a few seconds to a few minutes.

Contributions. We make the following contributions:

- We present HeteroSketch, the first system to our knowledge that performs coordinated sketch-based network-wide monitoring over a network of heterogeneous devices and caters to network dynamics. (§3)

- We develop a profiler that allows users to predict the performance of sketches on heterogeneous devices. (§4)

- We formulate a mixed-integer program to optimize sketch placement and resource allocation over heterogeneous devices and propose techniques to quickly optimize when topology, queries, traffic, or resources change. (§5, §6)

- We show that HeteroSketch is able to place tasks and allocate resources over network topologies, achieving greater scale and optimality than existing systems. (§7)

2 Background and Motivation

In this section, we describe how heterogeneous programmable data planes bring new opportunities and challenges to deploy network-wide monitoring under varying demands. We then discuss existing network-wide monitoring efforts.

Programmable Data Plane. Progress in programmable network devices is moving the network data plane towards a highly programmable infrastructure. This programmable infrastructure opens up the opportunity to develop measurement algorithms for a variety of fine-grained, flexible measurement tasks. For example, significant progress has been made in developing sketching algorithms [11, 12, 31] on the RMT architecture [32], where packets are processed over a series of reconfigurable match-action tables with user-defined actions in a pipeline. Similarly, multi-engine SmartNICs [18] consisting of a pool of general purpose processing elements (i.e., micro-engines) are a cost-effective option to allow hosts to offload monitoring capabilities or other parallel computation from CPU. These programmable devices enable the development of highly flexible and performant future-proof network-wide monitoring for various network demands.

New Requirements in Network-wide Monitoring. For a long time, network monitoring research has been focused on pursuing *accuracy* over other goals, such as forwarding *performance* with less computing and memory resources, and *scalability* by supporting larger-scale networks. While these requirements continue to be important, we believe that there are two significant roadblocks that make it difficult or impractical to use existing sketch-based designs at scale in future programmable data planes:

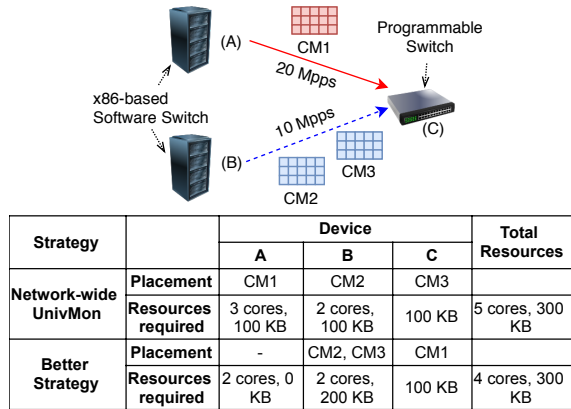
- *Heterogeneity in the network:* Network data planes are becoming increasingly heterogeneous with devices such as x86-based software switches [20], ASIC-based programmable switches [16], multicore system-on-chip (SoC) SmartNICs [18], and FPGA NICs [19, 27]. These devices are designed with diverse architectures and present very different resource bottlenecks to the programs that execute on them. The challenge lies in how to precisely character-


Figure 1: Example of network-wide UnivMon not optimally placing the sketches.

Strategy		Device			Total Resources
		A	**B**	**C**	
Network-wide UnivMon	Placement	CM1	CM2	CM3	
	Resources required	3 cores, 100 KB	2 cores, 100 KB	100 KB	5 cores, 300 KB
Better Strategy	Placement	-	CM2, CM3	CM1	
	Resources required	2 cores, 0 KB	2 cores, 200 KB	100 KB	4 cores, 300 KB

ize the performance of monitoring programs on current and possibly new devices and use these insights to optimize resource usage.

- *Network dynamics:* Network monitoring serves as a data collector and analyzer for other co-located network services (e.g., traffic engineering, load balancing, and anomaly detection). As all these services share the same infrastructure and their monitoring needs change, any network-wide monitoring system should quickly adjust to the following "network dynamics": (1) topology change, (2) monitoring query change, (3) traffic demand change, and (4) available resource change, in order to provide best monitoring performance and not interrupt other concurrent services.

Current Network-wide Monitoring and Limitations. In small networks, we can consider using techniques that record all packets or flows passing through the network for full accuracy (e.g., T-RAT [33], vCRIB [34], and OmniMon [35]). However, in practice, with the desire for *real-time* and *accurate* monitoring over large traffic volumes and dynamics, operators usually cannot afford to record all packets or flows on their network devices due to high resource usage and processing latency. Recently developed zoom-in techniques (e.g., Sonata [36] and ProgME [37], and others [38, 39]) provide no theoretical accuracy guarantee for dynamic traffic workloads. Systems such as NetFlow/sFlow [14, 15] and cSAMP [23] reduce overhead by recording only a fraction of packets via packet or flow sampling to compute measurement results. As shown in prior efforts [40, 41], these sampling approaches have low measurement accuracy in various tasks and workloads.

Sketching algorithms (sketches) address the drawbacks of sampling. At a high level, sketches [8, 9, 42] are probabilistic data structures that store a small summary of the input traffic. They allow a proven trade-off between the *accuracy* of supported queries and the *space* of the summary. Sketching techniques have efficiently supported various monitoring tasks including: heavy hitter detection [8, 9, 11, 12, 31, 43], traffic change detection [11, 44], anomaly detection [11, 22, 45],

Scheme	Resource Overhead	Heterogeneity & Dynamics	Memory-Accuracy Tradeoff
cSAMP [23]	High	✗	Poor
vCRIB [34]	High	Limited	Poor
OmniMon [35]	High	Limited	Poor
UnivMon [11]	Medium	✗	Good
HeteroSketch	Low	✓	Good

Table 1: Summary of qualitative comparisons of existing schemes and our approach (HeteroSketch).

entropy estimation [11, 46, 47], counting distinct flows [11, 12]. Most sketches mentioned above can be *linearly merged* to obtain aggregated results with the same additive error guarantees [48]. For example, Sketch 1 measuring flow set A can be merged with Sketch 2 measuring flow set B (e.g., by addition of the two counter tables) to obtain statistics about a combined flow set $A \cup B$, as long as Sketches 1 and 2 share the same hash and memory configurations.

Unfortunately, existing sketch-based monitoring solutions don't consider heterogeneity and dynamics, which affects their resource efficiency and/or accuracy (Table 1). For instance, Figure 1 shows a simple scenario where network-wide UnivMon [11] does no optimally place Count-Min Sketches [8], resulting in using 5 cores instead of 4. In this setting, we have three devices (CPU A, CPU B, and programmable switch C). We want 1 Count-Min sketch (CM1) to monitor traffic between devices A and C, and we want 2 Count-Min sketches (CM2 and CM3) to monitor traffic between devices B and C. We also assume that the programmable switch can only fit one sketch in its share of switch resources for monitoring tasks. CPU A requires 2 cores for forwarding 20Mpps while CPU B requires 1 core for 10Mpps. The key decision is which sketch should go on the programmable switch. *Better Strategy:* If we place CM1 on the switch, both CM2, CM3 run on CPU B consuming 1 core for sketching (combined 20M sketch operations per second). *Network-wide UnivMon:* If we place CM2 (or CM3) on the switch, then CM1 must be placed on CPU A consuming 1 core for sketching and CM3 (or CM2) must be placed on CPU B again consuming 1 core for sketching, for a total of 2 sketching cores. Note, placing only one of CM2 or CM3 on CPU B consumes 1 sketching core as cycles are wasted busy-polling for packets for performance reasons. UnivMon produces this placement as it tries to balance memory load across devices.

3 System Overview

We describe the high-level design of HeteroSketch and highlight the key challenges that the design must address.

3.1 Problem Scope

HeteroSketch provides a "One Big Switch" abstraction to the user, wherein the user can specify monitoring require-
Figure 2: HeteroSketch Overview.

ments over all or a subset of traffic flowing between network endpoints or *origin-destination (OD)* pairs. Monitoring requirements include the type of the sketch, flow filter, and accuracy requirement (Figure 2). HeteroSketch takes these monitoring requirements and assigns particular sketch-based tasks among the components of a heterogeneous network of diverse devices using state-of-the-art sketching algorithms such as Count-Min [8], Count Sketch [9], and UnivMon [11].

This abstraction can be used to manage network monitoring in various settings. For example, HeteroSketch could be applied by Internet Service Providers (ISPs) to manage monitoring services internally or for their clients. In this paper, we envision cloud providers being early adopters of our network-wide monitoring system. In a multi-tenant cloud environment, a cloud provider would be able to offer monitoring-as-a-service to the tenants. Tasks corresponding to queries from different tenants would be placed within the network as opposed to just on the end-hosts that the tenant is using, i.e., NIC and switch resources can be indirectly accessed by tenants for monitoring purposes. The operator would make control decisions using a centralized view to address different measurement objectives. For instance, the operator could (1) manage monitoring requirements submitted by multiple independent tenants while incorporating any potential contention between monitoring tasks placed on the same device; and/or (2) deploy their own monitoring tasks (e.g., detecting compromised tenant VMs [49]). In any of the scenarios, our system makes it possible to load balance monitoring tasks between servers, NICs, and switches, and to prioritize resources such as CPU cores for other critical services and cloud applications.

3.2 HeteroSketch Workflow

As depicted in Figure 2, HeteroSketch has two main components: a performance profiler and an optimization framework. **Performance Profiler (①) in Figure 2):** For any new device,

HeteroSketch needs to conduct offline performance characterization to add a new abstract profile into its device profile library. The device profile library allows HeteroSketch to predict the performance-resource trade-offs of different sketch configurations. We describe this Profiler in detail in Section 4.
Optimization Framework: Once HeteroSketch obtains user input as ② (monitoring requirements), the HeteroSketch Optimizer ③ outputs the configuration and mapping of sketches to devices (i.e., *sketch manifests* for each device) and the resources allocated to each device (i.e., *device configuration*). Based on the Optimizer output, HeteroSketch deploys sketches into the network and gathers network-wide statistics as other monitoring systems. If there are dynamic changes in user input, network topology, traffic demands, and available resources, HeteroSketch will perform a quick re-optimization ④. We describe this Optimizer in detail in Section 5.
Supported Queries: HeteroSketch currently supports sketch-based flow-level telemetry queries over flow sets defined over OD-pairs; e.g., heavy hitters, flow changes, entropy, distinct flows, among others, over flows across one or more OD pairs. For instance for network-wide heavy-hitters, a user can specify multiple OD-pairs to be monitored for the same query. HeteroSketch will then instantiate and collect (linearly merge) data from multiple instances of sketches (e.g., Count-Min and UnivMon) while ensuring that all OD-pairs are monitored and resource overhead is minimized. That said, telemetry queries that are not defined over flows, such as path-level queries in In-band Network Telemetry (INT) [50], or packet-level queries, which are not supported by sketches, are outside the scope of this paper.

3.3 Challenges and Key Insights

We describe the three main challenges that our design faces.
C1: [Heterogeneity] Predicting sketch performance for different resource allocations. Optimizing resource utilization requires characterization of exact costs and benefits of different deployment configurations. This is challenging because many characteristics of the program and the device architecture impact the processing time per packet.[1] For instance, devices may execute certain operations using ASICs and others using general purpose cores. The time for an instruction might depend on the allocated resources, e.g., memory access time depends on the working set. The program might have a complex, unpredictable control flow with many data dependencies. Past systems [28, 29] rely on low-level architecture specific counters and cache analysis to provide performance estimates. Such approaches do not provide the accuracy needed and would be difficult to generalize to other hardware.
    Insight: We observe that (1) the primitive operations of sketches (e.g., hashing, memory updates) largely determine

---

[1]We represent performance in terms of time per packet or inverse throughput and use these terms interchangeably.

packet processing time, and (2) based on data flow analysis, most sketches have limited data dependencies and limited control flow. This means that there are enough independent operations to be performed (either for the same packet or across packets), that performance is broadly determined by the number of operations rather than their inter-dependencies. Therefore, we design a benchmark suite consisting micro-benchmarks of primitive sketch operations for a small set of sketch manifests. The Profiler composes these benchmarks to generate algebraic characterization of the resource-performance trade-off for arbitrary sketch manifests.

C2: [Formulation & Scalability] The optimization formulation of sketch placement over heterogeneous hardware results in a large and complex NP-Hard optimization problem. Despite using a state-of-the-art commercialized solver (e.g., Gurobi), it still needs order of hours to finish even for relatively small networks (≈1000 nodes). Specifically, the complex *non-convex* device profiles and scale of the network slow down the optimization.

Insight: We use the solver's advanced features (bi-linear constraints) to incorporate the non-convex device profiles. For scalability, we partition the optimization problem into disjoint sub-problems which are solved concurrently. We define these sub-problems by partitioning the network into clusters. We find that traditional clustering techniques such as spectral clustering [51] either result in infeasible sub-problems or solutions which are far from optimal (see §6). Our key insight is to define clustering affinity between nodes based on OD-pairs (traffic and monitoring requirements) rather than just network structure.

C3: [Dynamics] Sketch manifests and device configurations can become stale due to network dynamics including changes in monitoring requirements, available resources, logical topology, and traffic demands. A robust solution should adapt its deployment at the rate of these changes.

Insight: While the insights in C2 help scale the Optimizer to handle large topologies and bring down solving time from order of hours to a few minutes (§7.2), we supplement the clustering approach with a *Fast Path* that allows quicker responses (in a few seconds) to network dynamics. It leverages our observation that it is sufficient to recompute the placement/configuration for only a subset of devices which are *directly affected* by the network dynamics (§6.2).

4 Performance Profiler

We leverage the common structure of sketches to make the performance prediction problem tractable. As an example, we describe the structure of a canonical Count-Min sketch [8] that can be used for maintaining a summary of per-flow sizes.

The sketch maintains a counter table of rows and columns. On observing a <*key*, *value*> pair, a hash function is computed over the *key* for each row of the sketch. These hash values are used to index into the rows and the content of the corresponding cells is incremented by *value*. The updates to different rows are completely independent of each other, which is similar for a large set of sketches [8, 9, 11, 13, 42, 52]. With this structure, hash computation and memory update operations consume the majority of the time.

Our Approach. While the common structure of sketches allows us to manage the complexity introduced from the program's side, we still need to manage the complexity due to diverse devices. Specifically, for each device type, we have a three-phase approach to determine the sketch performance:

- **Phase 1:** Measure the time for primitive operations.
- **Phase 2:** Compose the time for different operations.
- **Phase 3:** Consider impact of device configurations.

Before diving into the details of the three phases, we provide a brief overview of the Profiler's operation and its setup.

Setup: The Profiler uses a three-device testbed consisting of the device being studied (or device under test, DUT), a sender, and a receiver. The three devices connected in a linear topology with the DUT configured to forward traffic from the sender to the receiver. Such a setup can be created without a lab environment or re-wiring, by changing forwarding configuration in a local or cloud deployment. A more detailed description of this testbed is provided in §7.1.

Overview: The Profiler treats the devices as "black-boxes" and makes few assumptions about the architecture. We assume that the DUT has a library to implement sketch manifests and that it exposes an API to allocate resources. The Profiler uses this API to study the DUT's forwarding rate for a limited set of sketch manifest and device configuration combinations. The Profiler does not need any code instrumentation, hardware counters, or precise time-stamping, it simply studies the end-to-end forwarding rate.

For each device, the Profiler models time per packet as an algebraic function of *sketch parameters*, *device parameters* and *device configuration*. The sketch parameters include counts for primitive sketch operations, which are obtained from the sketch manifest (e.g., sketch type, the numbers of rows and columns [8, 9], and the number of levels (sketch instances) [11]). We obtain device parameters from micro-benchmarks for the primitive operations. Device configuration specifies the resources, including memory, processor cores, micro-engines, switch stages/ALUs, lookup tables, flip-flops, and/or DSPs. We believe this approach generalizes to support architectures beyond the hardware at hand (Table 2).

4.1 Detailed Design of the Profiler

Phase 1: Primitive Operations. In this phase, we evaluate the time for the following primitive operations per sketch update: hash computations (compute capabilities), memory accesses (impact of memory hierarchy), coin tosses (random

Type	Hardware
CPU (Open vSwitch)	Intel® Xeon® Silver 4110 CPU @ 2.10GHz (32KB L1, 256KB L2, 8MB L3 cache) with Mellanox ConnectX 4 NIC [53][20]
SoC SmartNIC	Netronome Agilio® CX 1x40GbE
FPGA NIC	Xilinx® Alveo™ U280 Data Center accelerator card
Prog. Switch	Barefoot Tofino

Table 2: Devices tested with Profiler.

(a) CPU   (b) SoC NIC   (c) FPGA NIC

number generation), and packet forwarding. For simplicity, we count the update to each row of a sketch as a separate *sketch update*, e.g., two Count-Min sketches with 4 rows each would make up 8 sketch updates per packet.

The Profiler studies the variation of time per packet as the configuration of a Count-Min sketch is varied. For hashing micro-benchmark (Figure 3), we vary the number of sketch updates for a small fixed amount of memory (to ensure memory does not become bottleneck). For the memory micro-benchmark (Figure 4a), we vary the sketch memory for a fixed number of sketch updates. We handle coin tosses similar to hashes but with sketches such as [13, 52] which rely on random number generation. Note, for all the micro-benchmarks, we generate flow keys that are uniformly distributed. This results in uniform memory access pattern for Count-Min sketch and allows us to estimate the worst case performance.

Phase 2: Composition. Given time for primitive operations from Phase 1, Phase 2 determines how different micro-benchmarks should be composed to obtain the total time per packet. The goal is to capture unique properties of how a device architecture combines the primitive operations by testing for three key properties: (1) Memory and compute concurrency, (2) Forwarding and sketching concurrency, and (3) Sketch access frequency. For each property, the Profiler defines a set of expected behaviors (composition functions). These correspond to different device architecture or sketch implementation choices. We currently rely on manually inspecting the micro-benchmarks to identify the device/implementation behavior. This process can be automated in a straightforward fashion. We detail the properties and behaviors below.

Memory and compute concurrency: Compute and memory operations in a system may be *coupled* or *decoupled* depending on the hardware: (1) in a *coupled* system, hashing and memory operations might contend for the same hardware units, (2) in the *decoupled* case, the memory and hash operations have zero contention, i.e.,

$$n_{sketch} = n_{compute} + n_{memory} \rhd \text{coupled}$$
$$n_{sketch} = \max(n_{compute}, n_{memory}) \rhd \text{decoupled}$$
$$n_{compute} = k_1 + u_h \cdot h$$
$$n_{memory} = k_2 + u_m \cdot T(m)$$

where n_{sketch} is the time for sketch updates, u_h is the number of hash computations per packet and u_m is the number of accesses to the sketch memory per packet. h is the time per hash computation, k_1 and k_2 are constants, and $T(m)$ is the time per memory access given m amount of total memory has been allocated for sketching. For the coupled case, the memory access benchmark would subsume the time for hashing and vice versa. In this case, $T(.)$ is used to represent *additional* time per memory access incurred due to potential cache misses. This is extracted by adjusting for the time per hash.

For CPU, we use the coupled model as hash computation has memory instructions which prohibit full overlap with sketch memory accesses. For the FPGA and SoC SmartNIC, we use the decoupled model, as their compute (hashing) units and memory units are completely disjoint.

For sketches which have multiple levels or control paths (e.g., UnivMon [11]), the number of primitive operations can be different for different packets based on their flow key as well as the sketch memory access pattern can be non-uniform even for uniformly distributed flow keys. In this case we interpret u_h, u_m as the expected number of operations per packet and use T(Effective uniformly accessed memory) instead of T(Total memory). For brevity we discuss the details of computing "effective uniformly accessed memory" in Appendix B. We find that UnivMon behaves as if at most 4 of its levels are accessed uniformly irrespective of the amount of sketch memory and across devices.

Forwarding and sketching concurrency: Packet forwarding and sketching can be done in parallel or in the same thread(s). If done in parallel, the time per packet would be the maximum of the inverse throughput of forwarding and sketching; otherwise, the sketching benchmarks would subsume the time for forwarding, i.e.,

$$N = \max(n_{fwd}, n_{sketch}) \rhd \text{concurrent}$$
$$N = n_{sketch} \rhd \text{sequential forwarding and sketching}$$

where N is the time per packet and n_{fwd} corresponds to the forwarding inverse throughput. For both SoC SmartNIC and CPU, sketching is done on the critical path (sequential). On the FPGA NIC sketching is off the critical path (concurrent).

Sketch access frequency: Not all sketches may be updated for every packet. For instance, the user may want certain sketches to only monitor a subset of packets forwarded by a device (users specify this by providing a *flow filter* for each sketch). This is incorporated by summing u_h, u_m weighted by the probability that a sketch is updated for a particular packet. This probability is calculated based on the flow filter and traffic matrix to obtain the fraction of packets which satisfy

the flow filter. If this cannot be computed due to granularity of traffic matrix, we keep one additional counter per sketch that counts the number of packets that update the sketch.

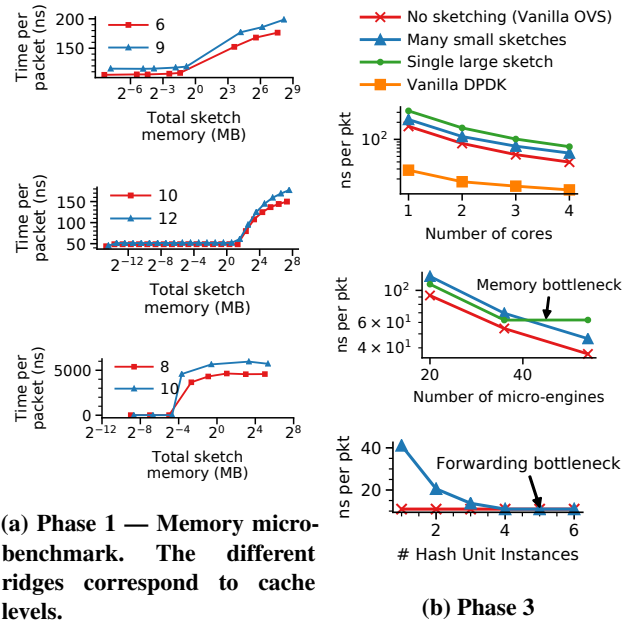
Phase 3: Device Configuration. The Profiler must also build a model for how sketching and forwarding performance scales with device configuration (e.g. CPU cores, micro-engines). Since performance scaling may differ across bottlenecks, we study three sketch manifests: (1) Small sketches, which trigger compute bottlenecks; (2) Single large sketch, which trigger memory bottlenecks; and (3) No sketch, to study forwarding bottlenecks. Figure 4b shows these measurements for software switch, SoC smartNIC and FPGA NIC.

Based on these measurements, the Profiler estimates f, the fraction of parallelizable execution time by fitting Amdahl's law, and updates each of n_{fwd}, $n_{compute}$ and n_{memory} to include the effect of parallelism. For instance $n_{compute}$ (from Phase 1) becomes:

$$n_{compute} = (k_1 + u_h \cdot h)[(1 - f_c) + \frac{f_c}{c}]$$

where f_c is fraction of parallelizable execution time when compute is bottleneck. We find that $f \approx 1$ for the software switch when any of forwarding, compute or memory is the bottleneck. For the SoC NIC, we find that f is ≈ 1 when forwarding or hashing is the bottleneck. However, when memory is the bottleneck, increasing micro-engines does not change packet rate, implying that f is 0 (Figure 4b). This is consistent with the fact that there is a single cache and DRAM (where sketch memory is allocated) – shared by all micro-engines – which becomes a bottleneck, as opposed to cores on a CPU which have their own caches, which allows for parallelism even when memory is the bottleneck. For the FPGA NIC, f is ≈ 1 when hashing is bottleneck otherwise it is 0. We measure the compute resources of FPGA in the units of a hash unit instance, each consuming 5 digital signal processors, 214 lookup tables, and 486 flip-flops.

Summary. The final relations encoding time per packet N in terms of number of operations u_h, u_m, sketch memory m and device parameters (h, $T(.)$, f's, constants) and device configuration are referred to as *device profiles*. This algebraic characterization of performance-resource trade-offs is used by the Optimizer for deciding sketch placement and resource allocation. In our current formulation, we don't explicitly model the impact of contention from non-monitoring tasks. We assume that compute resources are pinned to sketches and memory resources are explicitly allocated using technologies akin to Intel Cache Allocation Technology [54]. We also don't study the overhead of such isolation mechanisms.

Programmable switch [16] is a special case here as its resources are allocated by the compiler with guaranteed constant time per packet. Thus, the Profiler only needs to model the resources for different sketching manifests based on the resource usage output of the compiler.


(a) **Phase 1 — Memory microbenchmark. The different ridges correspond to cache levels.**

(b) **Phase 3**

Figure 4: (a) Phase 1 — CPU with single core running OVS and sketching module (top), SoC NIC with 54 micro-engines (middle), FPGA with 10 hash instances (bottom). The numbers in the legend correspond to the number of sketch updates per packet.

(b) Phase 3 — Inverse throughput as CPU cores (top), SoC NIC micro-engines (middle) and FPGA hash unit instances (bottom) are varied. For FPGA NIC, single large sketch (not shown due to scale) is a flat line (memory bottleneck).

5 Optimizer

The goal of the Optimizer is to decide which sketch should be placed on which device and which resources each device should use while meeting the device constraints, monitoring requirements, traffic demands, and optimizing towards user-specified goals. We formulate the placement and resource allocation problem as a Mixed-Integer Bi-linear program (MI-BLP), which is defined below with constants and variables described in Tables 3 and 4 respectively. While we investigate resource usage as an objective for concreteness, our formulation can be easily tweaked to handle other objective functions (Equation 7 in Appendix C).

Input: The input has the following three key features: (1) set of *devices* $\mathcal{D}$ in the network, along with their profiles generated using the Profiler (§4) and resource availability; (2) set of needed *sketches* $\mathcal{S}$, along with their configuration; (3) set of *Origin Destination (OD) pairs* $\mathcal{P}$.

In particular, each OD-pair is uniquely specified by: (1) device-level path in the network, (2) rate of traffic demand on that path, (3) set of sketches that should monitor traffic that is part of this OD-pair. With the OD-pair abstraction, we can handle the following cases:

- If there are multiple paths between an OD-pair, logically

$$\text{O1: resources} \quad \text{Minimize} \sum_{d \in \mathcal{D}} (res_d + mem_d), \quad \textbf{s.t.} \quad (1)$$

$$\text{C1: coverage} \quad \sum_{d \in p_\pi} b_{(d,s)} \geq 1 \quad \forall p \in \mathcal{P}, \forall s \in p_s$$

$$\text{C2: accuracy} \quad mem_{(d,s)} \geq s_{mem} \cdot b_{(d,s)} \quad \forall s \in \mathcal{S}, \forall d \in \mathcal{D}$$

$$\text{C3: capacity} \quad \sum_{s \in \mathcal{S}} b_{(d,s)} \cdot s_{rows} \leq d_{rows}, \quad \text{and}$$

$$mem_d = \sum_{s \in \mathcal{S}} mem_{(d,s)} \leq d_{mem} \quad \forall d \in \mathcal{D}$$

$$\text{C4: profiles} \quad \forall d \in \mathcal{D}:$$
$$time_d = d_{time}(res_d, \mathcal{P}_d, \{(mem_{(d,s)}, b_{(d,s)}) | s \in \mathcal{S}\})$$

$$\text{C5: traffic} \quad time_d \leq \frac{1}{d_{\text{traffic}}} \quad \forall d \in \mathcal{D}, \quad \text{where}$$
$$d_{\text{traffic}} = \sum_{p \in \mathcal{P}_d} p_t, \quad \mathcal{P}_d = \{p | d \in p_\pi, p \in \mathcal{P}\}$$

Symbol	Interpretation
$\mathcal{D}, \mathcal{S}, \mathcal{P}$	Set of devices, sketches, and OD-pairs
p_s	Set of sketches for OD-pair p
p_π	Device level path for OD-pair p
p_t	Rate of traffic relevant for OD-pair p
s_{mem}, s_{rows}	Memory required for desired accuracy & number of rows for sketch s
d_{mem}	Maximum memory on device d
d_{rows}	Maximum rows that can fit on device d
d_{time}	(Function) representing the device profile (§4) for d (Time per packet in seconds)
$\mathcal{P}_d$	OD-pairs which pass through d
$d_{traffic}$	Total traffic rate in packet per second (pps) witness by device d

Table 3: Constants.

Domain	Symbol	Interpretation
$\mathbb{R}_{\geq 0}$	$mem_{(d,s)}$	Memory of sketch s on device d.
$\{0,1\}$	$b_{(d,s)}$	Is sketch s placed on device d
$\mathbb{Z}_{\geq 0}$	res_d	Resources allocated to device d, (e.g., processing cores, stages, functional units etc.)

Table 4: Variables.

distinct OD-pairs can be instantiated for each separate path.

- If part of the traffic in an OD-pair needs to be monitored by sketch A and other part using sketch B, then two logically distinct OD-pairs can be instantiated with the same path but specifying different sketches along with the appropriate rate of traffic which is relevant to each sketch.

- If the same query or sketch needs information about traffic on multiple OD-pairs, each OD-pair can refer to the same sketch identifier.

- Multiple sketches can monitor traffic in a single OD-pair. This would be used in the cases when we need to maintain a statistic for different dimensions of the same traffic (e.g., dimension 1: distribution of DstIPs for each source and dimension 2: distribution of SrcIPs for each destination).

This input is compiled from the high-level measurement requirements specified by the user. The traffic demands (packet rates) are estimated using the traffic matrix and the paths are obtained using the routing information and flow filters specified for each sketch by the user.

Outputs and constraints: The Optimizer decides which sketch should be placed on which device. This is indicated through variables $b_{(d,s)}$. While doing so, the Optimizer ensures that for each OD-pair, each sketch of that OD-pair is placed on at least one of the devices lying on the OD-pair's path (C1: flow coverage in Equation 1). The memory for each sketch is directly determined by the accuracy required for that sketch (C2: monitoring accuracy). Each device is constrained by memory capacity and some devices may have constraints on row capacity (e.g., due to limited stages in programmable switch) (C3: device capacity). C4 (device profiles) encodes the relationship between time per packet, the sketch parameters, device parameters and the device configuration as described in Section 4. The processing overhead on each device should be such that the overhead does not stall the traffic flowing through the device (C5: forwarding performance). Note that C4 is natively expressed through Gurobi's API using piece-wise linear [55] and bi-linear constraints [56]. We elaborate on this in Appendix C.

Measurement Accuracy: Different feasible solutions may deploy sketches at different locations in a network (e.g., Figure 1) and even create multiple instances of the same sketch. We note that our sketch placements make no impact on the monitoring accuracy. This is because, these multiple instances are linearly merged (§2) at the central controller. The merge is possible as instances of the same sketch share the same hash functions, memory configuration. The merge does not lead to over/under counting as we ensure that each packet updates exactly one instance of all the required sketches. This is ensured as: (1) constraint C1 guarantees that there is at least one instance of the required sketches on the path of each OD-pair, and (2) we generate sketch manifests so that exactly one of these instances is chosen (arbitrarily) to be updated for each OD-pair.

6 Scalability and Dynamics

Solving the MI-BLP in Gurobi can take more than a few hours even for modestly sized data center topologies with thousands of devices. For quick responses to network dynamics and scaling to more devices, we use a three step approach:

- *Step 1*: Partition the network topology into disjoint clusters
- *Step 2*: Run Optimizer to assign sketches to the clusters[2]
- *Step 3*: For each cluster, run Optimizer to place sketches onto devices *within* the cluster.

Since the placement decision for each cluster is done independently, Optimizer instances can be spawned in parallel,

---

[2]For this step, the traffic demands and device profiles (C4-5 in equation 1) are not used, as the Profiler does not model the performance of clusters.
Figure 5: Different ways to cluster a graph.

which makes this approach scalable. Note that, Step 2 itself can consume significant time if the number of clusters is large. We address this by recursively applying Step 1 and 2 to build a hierarchy of clusters. We determine the threshold to apply the recursive step by modeling the cluster size-compute time relationship (Figure 14 in Appendix A) and choosing the largest cluster size with an acceptable run-time. We also add a *fast path* for quick response to cater to network dynamics that *directly affect* only a small subset of devices.

6.1 Clustering Approach

Partitioning the network devices into clusters will inevitably hide some details about the topology and create a trade-off between optimality and solving time. This is because when the Optimizer is run to place sketches onto the cluster (Step 2), it may choose a sub-optimal (or even infeasible) cluster as it does not know what is inside the cluster. Ideally, we want to cluster the topology in a way that significantly accelerates the solving process while incurring minimal optimality loss.

Clustering Examples. We observe that naïvely clustering the topology graph based on the hierarchy of the topology or applying graph clustering algorithms (e.g., spectral clustering [51]) can lead to sub-optimal or even infeasible sub-problems. Figure 5 illustrates this in an example topology of 7 devices. In this example, the edges show the paths of the OD-pairs and the colors (or line-styles) of the edges correspond to different OD-pairs. We need to deploy 2 sketches, each of which monitors one of the OD-pairs shown in blue (solid) and red (dotted).

Simple clustering: By directly applying spectral clustering on network topology, we obtain the result in Figure 5(b). Based on this clustering, assume that in *Step 2*, the Optimizer decided to place one sketch on cluster (3,4) and the other sketch on cluster (5,6). Further assume that the sketch placed on cluster (3,4) monitored the red OD-pair. When the Optimizer again runs *Step 3* for devices within cluster (3,4), since only device 3 sees packets on the red path, the sketch for the red OD-pair can only be placed on device 3. If device 3 is currently not available to place the sketch or device 6 is in fact a better allocation, the simple clustering will lead to an infeasible or sub-optimal solution.

Better clustering: If we cluster as Figure 5(c), the sketch for the red (dotted) OD-pair could be assigned to cluster (3,6) and the Optimizer running within that cluster retains its freedom to place the sketch on device 3 or 6.

Our Design. We learned from the above example that we should keep nodes that *communicate* with each other in the same cluster, where communicate means that there is an OD-pair that has a path connecting the nodes. This should be done irrespective of the number of network-level hops (physical or logical links) between them. This provides the Optimizer in *Step 3* additional placement choices for sketches within the cluster sub-problem.

We can incorporate communication affinity by applying spectral clustering on the communication graph (G_c), where vertices are network devices, with edges between all pairs of devices which communicate with each other. While this approach works for general network environments, we find that spectral clustering itself is time consuming for large networks [57]. Thus, we imitate spectral clustering using a domain-specific heuristic and are investigating faster alternatives and implementations of spectral clustering.

Our heuristic is based on the observation that many clustering solutions preserve enough flexibility for sketch placement yielding good performance (Figure 12 in Appendix A). This observation was made when exploring the space of possible clustering solutions and their impact on MIP objective using simulated annealing [58]. Our heuristic works in a multi-tenant setting where tenants share the network but not the end-hosts. For building clusters, we instantiate a cluster for end-hosts of each tenant. Then, to ensure clusters are evenly sized, we arbitrarily merge (or split) the clusters if they are too small (or big). Finally, the switches and NICs are assigned to the cluster of the end host with which they have highest affinity. In Appendix A, we discuss how to choose cluster sizes and provide examples of clustering output for different clustering techniques.

6.2 Fast Path

The Fast Path further improves response time for network dynamics including: (1) Topology change in the path (e.g., VM migration); (2) Monitoring query (sketch) change from the user/operator; (3) Traffic change in the OD-pair (e.g., traffic demand variations); (4) Available resource change due to the dynamics of other non-monitoring services running on the shared devices. (1)–(3) reflect as changes in OD-pairs ($\mathcal{P}$) and (4) reflects as changes in devices ($\mathcal{D}$).

The key observation we have from §6.1 is that sub-problems should preserve enough placement choices for sketches. Based on that, we find that, on network change events, recomputing placement only for the set of devices $\mathcal{A}$ *directly affected* by the changes is sufficient. We compute this set through the following process: (a) For each changed device $d \in \mathcal{D}$, we add d to $\mathcal{A}$ and, for each sketch s currently placed on d, we add the OD-pair(s) monitored by s to the set of changed OD-pairs. (b) For each changed OD-pair (due to previous step or otherwise), we add all devices specified in the path of the OD-pair to $\mathcal{A}$. The Optimizer is then run

only for the devices in set $\mathcal{A}$ and the sketches specified in the changed OD-pairs, including the sketches already mapped to devices in $\mathcal{A}$.

7 Evaluation and Implementation

We implement HeteroSketch and evaluate its effectiveness. Our major findings are as follows:

- HeteroSketch's Profiler accurately characterizes the performance of devices across a variety of sketch manifests and device configurations (§7.1)
- HeteroSketch's Optimizer is able to (1) reduce resource footprints and obtain feasible solutions when prior approaches fail, and (2) scale to large topologies (> 40,000 devices) while preserving good quality solutions. (§7.2)
- HeteroSketch's Fast Path allows prompt responses to network dynamics including changes in topology, traffic, query, and available resources. (§7.3)

Implementation. For the software switch, the sketching modules are implemented as a part of the OVS data plane. For the SmartNIC, we use the internal and external memory regions for storing sketch state as these are accessible from all the micro-engines unlike local and island-specific memory regions. The Optimizer is run on an Intel® Xeon® CPU E5-2680 v2 processor @ 2.80GHz with 128 GB RAM.

7.1 Performance Profiler

Setup. This evaluation uses the same three device setup introduced in §4 which was used to create the device profiles (Table 2). We use dpdk-pktgen [59] to generate traffic and configure dpdk-testpmd [60] to measure receive rate. The sender generates min-sized (64 Byte) packets to measure the maximum packets per second that can be processed. We use source IPs as the flow keys for the sketches, which are taken from a uniform random distribution. This is done in order to use the Optimizer to allocate resources for worst-case (uniform) traffic scenarios. We discuss in Appendix B, how other traffic distributions could be accommodated.

Workloads. For generating sketch manifests, we consider a range of configurations for three different types of sketches: Count-Min, Count Sketch and UnivMon. For each sketch, we vary the number of rows from 1 to 12 and, for memory, we vary the counters per row from 1 to 2^{22} (≈ 4 million) in steps of powers of 2. For UnivMon, we vary levels from 2^2 to 2^5 in steps of powers of 2. For generating device configurations, we vary the SoC NIC micro-engines from 20 to 54, for the software switch, vary cores from 1 to 4, and for the FPGA NIC, vary maximum allowed hash instances from 1 to 12. Large number of rows emulate multiple sketches per device.

Results. Table 5 summarizes the results of the experiments and Figure 6 shows results for a subset of the experiments.

Sketch	CPU	SoC NIC	FPGA
Count-Min Sketch	3.08, 9.63	3.68, 12.99	1.9, 4.1
Count Sketch	5.61, 8.51	1.26, 4.51	2.2, 4.14
UnivMon	2.80, 6.38	2.38, 3.75	2.28, 5.88

Table 5: Profiler Evaluation — Each sketch–device combination reports the (mean, 90th percentile) of percent error $\left(\left|\frac{actual-model}{actual}\right| * 100\right)$ for the time per packet metric.

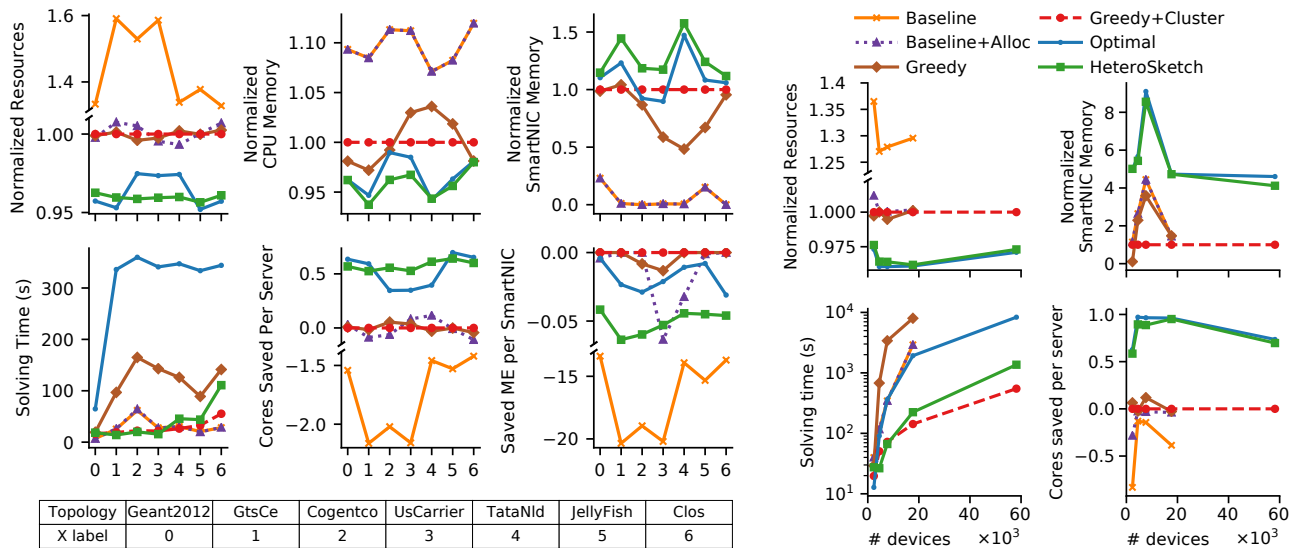
(a) 2 Cores   (b) 4 Cores
Figure 6: Performance Profiler — CPU model evaluation for Count-Min Sketch.

Figures for additional experiments can be found in Appendix B. These figures compare the time per packet estimated by the Profiler's model and the ground truth. Over all the combinations of sketch manifests and device configurations, the Profiler's model is within 5.61% of the ground truth on average and within 13% in the tail cases. We don't show results for programmable switch as it guarantees line rate if the program fits (which is captured by the capacity constraints in the Optimizer). We observe that most profiling errors occur in larger sketch configurations, when off-chip memory is used. Based on our estimates, such errors would disturb the resource allocation for less than 5% devices when profiles are off by 10%. We discuss the impact of profiling errors on the Optimizer in more detail in Appendix B.

7.2 Optimizer

We evaluate the solutions generated by the Optimizer on two key metrics: (1) resource-efficiency benefits and (2) the optimization run time. We use the device profiles to estimate the resource usage and performance for the sketch placements generated by different optimization schemes. We use the following methodology to generate input scenarios:

Topologies. We conduct two studies: (a) *Topology* – variation with topology structure. We use selection of topologies from the Internet Topology Zoo [61], JellyFish [62] and a three-level Fat-Tree data center topology (Clos) [63, 64] (Figure 7a). (b) *Scale* – variation with topology size. We use a Clos topology with varied degrees (number of *pods*) from 16 to 48 (Table 6, Figure 7b). We extend the Points-of-Presence (POP) topologies [61] to include servers and NICs based on principles from [65].

For both studies, we focus on a multi-tenant setting, where different tenants submit monitoring tasks to a central system (e.g., the cloud or Internet service provider). This allows us


(a) **Topology Study** — The Clos topology used has 20 pods, JellyFish has the same number of devices as the Clos topology (2000 servers/NICs each and 500 switches). Note, a time limit of 300s for the MIP solver was used.

(b) **Scale Study** — These experiments were performed on inputs described in Table 6.

Figure 7: Optimizer Evaluation — Compute resources are shown in terms of amount saved relative to Greedy+Cluster (negative compute resources implies more resource consumption than Greedy+Cluster). Total resources and memory resources are normalized w.r.t Greedy+Cluster. Both sub-figures share the same legend. Additional details in Appendix C (Figures 20 & 21).

Fat-tree Degree	Sketch load (Y)	Servers / NICs	Switches	Total devices
16	1	1,024	320	2,368
20	3	2,000	500	4,500
24	3	3,456	720	7,632
32	4	8,192	1,280	17,664
48	4	27,648	2,880	58,176

Table 6: Topologies and Workloads.

to stress test the schemes under a diverse set of monitoring requirements. We assign X servers to each tenant where X is taken from the uniform distribution $\mathcal{U}(6, 12)$. We set the capacity of each server link to 25 Mpps (64B packets). This is equivalent to the throughput of vanilla OVS with 4 cores. We randomly assign half of the servers with the SoC SmartNIC and other half with the FPGA NIC.

Monitoring requirements. The total number of queries (sketches) is set equal to Y times the number of servers in the network. These monitoring tasks are evenly partitioned among the tenants. We vary the sketching load (Y) between 1 (low) and 4 (high). Low load is used to study the system when each device in the network runs much below the total monitoring capacity they can handle. High load is used to study the system under stress. Table 6 shows the load used for different topologies. The monitoring tasks are equally divided between Count-Min, Count Sketch and UnivMon sketches.

OD-pairs. Each tenant specifies M OD-pairs from the set of servers assigned to them, where $M \sim \mathcal{U}(64, 96)$ and each OD-pair is monitored by K randomly chosen sketches of the tenant where $K \sim \mathcal{U}(1, 3)$. Since we don't have access to the monitoring demands from different operators, we select

OD-pairs, routes (paths) and traffic demands iteratively to ensure: (1) traffic is evenly distributed between OD-pairs, and (2) link utilization is at least 90% to stress the system.

Compared Schemes. As shown in Figure 7b, we compare HeteroSketch (6) against five other schemes (1)–(5):

(1) Baseline: Capacity-aware placement with *static* resource allocation, i.e., placing sketches to minimize the sketch memory with compute resource assigned apriori to cores=5, micro-engines=54 (equal to resources exposed to Optimizer). This is closest to UnivMon [11].

(2) Baseline+Alloc: The placement of sketches is done in the same manner as in Baseline. Instead of static resource assignment, just enough resources are allocated to meet the traffic and sketching demands based on the device profiles. This is used to investigate benefits obtained solely from profiling-aware resource allocation.

(3) Greedy: This is a strawman extension to the baseline which prioritizes placing sketches on programmable switches over CPUs and SmartNICs because of their line-rate guarantees. Resource allocation is done using device profiles similar to Baseline+Alloc. Prioritizing sketch deployment on switches is a reasonable heuristic when sketch load (Y) is low (first data point of Figure 7b, gap between resource usage for Baseline+Alloc and Greedy).

(4) Greedy+Cluster: To compare the optimality of our scheme to prior work for larger topologies, we extend the Greedy strategy to use our clustering optimization.

(5) HeteroSketch w/o clustering (Optimal): Joint placement and resource allocation using the formulation in Equation 1

Sketch	CPU	SoC NIC	FPGA	Switch
Count-Min	4112	2001	2111	1563
Count	4172	2066	2106	232
UnivMon	4169	2120	2049	143

Table 7: Sources of benefits (Sketch-Device Affinity) — Total number of sketches on each device. (Clos $pods = 16$, $Y = 4$.)

without the clustering approach.

(6) HeteroSketch: Joint placement and resource allocation with the clustering optimization.

Results. In Figure 7, we can see that HeteroSketch is able to lower resource utilization significantly (close to optimal) and saves between half to one CPU core per server on average compared to Greedy+Cluster ($20-30\%$ improvement). Compared to Baseline, HeteroSketch saves around 2.5 cores per server and about $15-20$ micro-engines per SoC NIC ($40-60\%$ improvement). It accomplishes this without incurring significant time to compute the placement of measurement tasks even as topologies scale to more than 40k devices. We compute total resources (HeteroSketch MIP objective) as a weighted sum of all devices resources including CPU cores, micro-engines, FPGA hash unit instances and memory, and normalize it by the total resources used by Greedy+Cluster. This is shown as *normalized resources* in Figure 7.

Sources of Benefits. We explore the benefits obtained from different features of HeteroSketch.

Bottleneck awareness: The device profiles are successful in incorporating capabilities of different device architectures, this allows HeteroSketch to allocate just enough resources to meet the sketching and forwarding demands. The gap in normalized resources between Baseline and Baseline+Alloc in Figures 7a and 7b demonstrates benefits attained solely from profiling aware resource allocation. For instance, on the SoC SmartNIC, when memory is the bottleneck, more micro-engines do not improve forwarding performance (Figure 4b).

Efficient use of resources: We see from Figure 8a that HeteroSketch allocates 20% fewer CPU cores (8k vs 10k cores) but uses the cores it allocates more effectively (each core is >80% utilized). Specifically, on the software switch, the cores are configured to poll NICs for packets (for performance reasons), as a result, CPU cycles are wasted busy polling when there are no packets in the NIC buffers. With the help of device profiles, the Optimizer is able to consolidate load towards cores which would otherwise waste cycles. Similar trends are observed for other resources including SoC memory bandwidth (Figure 8b), and SoC micro-engines (Figure 8c).

Ability to trade-off resources: For the scale study (Figure 7b), we set lower weightage to SoC SmartNIC memory relative to the topology study (Figure 7a). We observe in Figure 7b that HeteroSketch is able to incorporate this by saving more number of cores per server at the cost of SoC SmartNIC memory usage.

Sketch-Device affinity: We show the number of sketches instantiated of each type on each device in Table 7. Recall that

(a) CPU Utilization.

(b) SoC SmartNIC Memory Bandwidth Utilization.

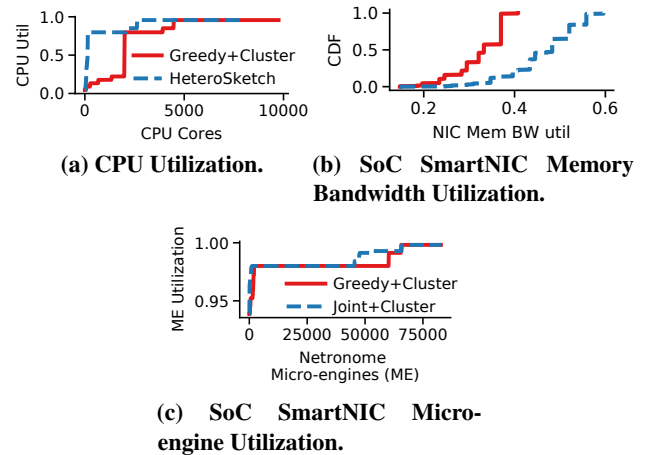
(c) SoC SmartNIC Micro-engine Utilization.


Figure 8: Sources of Benefits (Efficient use of resources) — (Clos $pods = 20$).

the monitoring requirement specified equal number (≈ 1360) of queries for each sketch type. Multiple instances of each sketch are created to meet the coverage requirements. We make three key observations here: (1) HeteroSketch tries to place heavier sketches (e.g. UnivMon) on better vantage points so as to reduce the total required instances. (2) The switch statically allocates resources to each sketch while other devices can share resources across sketches. Due to this HeteroSketch places less number of sketches on the switch, especially for Count Sketch and UnivMon due to more number of operations. (3) HeteroSketch instantiates relatively more number of UnivMon sketches on CPU and SoC SmartNIC as they have relatively larger and faster memories.

Clustering Algorithm. Figure 7b and 7a also suggest that our clustering technique does not significantly degrade resource efficiency. Clustering imposes a trade-off between optimality and solving time which we explore in more detail in Appendix A. We see in Figure 7a, that HeteroSketch finds better solutions than the Optimal scheme when configured with a time limit, achieving a better trade-off between optimality and solving time than the MIP solver.

For evaluating the Optimizer, we used the multi-tenant clustering heuristic developed in §6.1. We investigated use of other algorithms to cluster the communication graph (§6.1) including KMedoids, HDBSCAN, modularity maximization [57, 66]. Unfortunately, these techniques yield infeasible sub-problems in Step 3 of §6.1 for the inputs that we used.

Note, while it is true that our assumption about one server being solely used by one tenant makes the optimization problem instance easier, despite that, the MIP solver still needs explicit guidance in the form of clustering for speed up. This can be seen from difference in solving time with and without clustering in Figure 7.
Figure 9: Dynamics — variation with number of changes in succession (Clos topology with 16 pods).
Figure 10: Dynamics — variation with topology size for a single change. Negative objective gap means that Fast Path consumes less resources than full re-run. This can happen because both use the clustering heuristic which does not guarantee strictly optimal solutions. (Conducted on topologies in Table 6.)

7.3 Dynamics - Fast Path

As described in §6, changes in OD-pairs can correspond to changes in traffic, monitoring requirement, and topology. To generate such changes, we generate inputs for the Optimizer as described in §7.2. Then, we randomly keep $10n$ of the generated OD-pairs aside to serve as change batches, where n is the number of batches and each batch has 10 changed OD-pairs. We also generate resource availability changes in each batch by randomly sampling 10 devices and randomly increasing/decreasing their resource availability (e.g., micro-engines/memory) by 20%. We find that changes in a batch amount to roughly 50 to 150 devices being directly affected ($|\mathcal{A}|$ in §6.2) across the topologies in Table 6. In general, $|\mathcal{A}|$ can depend on the size of the topology and monitoring requirements. For the Clos topology, since path lengths are equal irrespective of number of pods, we see little dependence of pod count on $|\mathcal{A}|$.

Despite being run only for the subset of affected devices, successive runs of the Optimizer don't diverge from the global solution generated by re-running the Optimizer over the entire topology using clustering (Figure 9). Further, the response time to cater to dynamics is reasonably low with the Fast Path even as we scale the topology size (Figure 10). The Fast Path uses the clustering optimization when the set of affected devices is larger than the optimal clustering size and can amount to a full run of the Optimizer in the worst case. Fast Path, together with the clustering heuristic enables a response time of a few seconds (the set of affected devices is small) to a few minutes (when run over entire network). Note, within the scope of this work, we don't study how the new placement can be configured consistently and quickly. These are active areas of research [35, 67].

8 Other Related Work

Other related work not covered in §2 can be classified into four categories:

Sketch resource allocation. SCREAM [68] allocates memory for a sketch based on temporal and spatial changes in traffic moments for a fixed sketch placement. Open Sketch [10] optimally selects sketch algorithm and configuration for a given query. Both are complementary to our work.

Sketch implementations for different hardware. Our work relies on state-of-the-art implementations of sketches for different hardware. Fortunately, recent efforts [12, 13, 22] have focused on addressing the bottlenecks of sketching algorithms in software switches and have demonstrated efficient implementations in programmable switches or NICs [11, 12, 31].

Other work in network monitoring. HeteroSketch's goal is to support network-wide flow monitoring. Numerous complementary efforts focus on either fine-grained and adaptive flow monitoring (e.g., [36, 38, 69]), diagnosis (e.g., [70–72]), or network performance-related objectives (e.g., [73, 74]).

Efforts in speeding up network-wide optimizations. Concurrent with our work, Abuzaid et al. in [75] explore the use of clustering to speed up network flow problems. While our work tries to maintain feasiblity of sub-problems through carefully deciding which devices to cluster together, they impose additional constraints while conducting flow allocations over clusters to ensure that the subsequent sub-problems are feasible. We leave exploration of such a technique in the context of sketch placement for future work.

9 Conclusions

We observe that existing efforts on sketch-based network-wide monitoring remain impractical as they fail to cope with the key requirements of heterogeneity and dynamics in the network. We propose HeteroSketch as a coordinated solution to achieve optimized task placement and resource allocation over heterogeneous networks. HeteroSketch precisely characterizes the performance of sketches on diverse devices and is integrated with a clustering technique to handle networks scale and dynamics. Our evaluation demonstrates that HeteroSketch scales to toplogies with tens of thousands devices with near optimal resource efficiency. We posit that our system can more generally be applied to allocate resources for other networked applications in heterogeneous networks, and we plan to explore this for future work.

(a) Spectral Clustering on Topology **(b) Spectral Clustering on Communication Graph** **(c) Clustering using multi-tenant heuristic**
Figure 11: Output of clustering

A Clustering Details

Clustering Heuristic. We performed simulated annealing to explore the space of clustering solutions. Figure 12 shows the annealing in action. We find that there are many clustering solutions that result in optimization solutions which are close to optimal.
Figure 12: Simulated Annealing — Spectral-topo refers to spectral clustering over network topology. Similarly, Spectral-comm is over the communication graph. Multi-tenant refers to our domain specific heuristic. Optimal refers to no clustering.

Clustering Output. Figure 11 illustrates examples of the clustering output for different clustering techniques. The topology shown is a simple tree topology with only servers and switches (without NICs) for ease of visualization. The nodes marked '0' are switches and the other nodes are servers. The non-zero numbers on the servers signify that servers with the same number are communicating with each other. The colors signify that devices having the same color are in the same cluster.

Optimality vs. Solving Time Trade-off. Figure 7b and 7a also suggest that our clustering technique does not significantly degrade resource efficiency. This is counter-intuitive since clusters limit the types of optimization possible. We explore this in in Figure 13. Cluster size represents a trade-off between optimality and solving time, i.e. smaller clusters help reduce solving time at the cost of optimality. We observe

that the even for relatively small clusters (20 devices), the optimality gap is very low ($< 0.4\%$), allowing us to choose small clusters to reduce the run-time while preserving close to optimal solutions. The extreme case of all devices within the same cluster mimics the case of no clustering. In this case, all sketches would be assigned to the only available cluster and then the Optimizer is run to place sketches on the devices within that single cluster, effectively deciding between all devices of the topology.

The MIP solver also natively allows trading-off solving time for optimality through configuration of a time limit. In Figure 7a, we configured a time limit of 300s. We find that HeteroSketch is able to produce better quality solutions in lesser time, achieving a better trade-off between optimality and solving time.
Figure 13: Cluster size — optimality gap vs runtime. The optimality gap is the gap between the objective of HeteroSketch relative to the objective value of Optimal. (For experiment with $pods = 24$).

Choosing Cluster Size. As we see in Figure 13, the clustering heuristic provides a trade-off between solution quality (optimality) and optimization run-time. We want to be able to select the largest cluster size which allows an acceptable run-time. To do this, we look at the knee of the graph between solving time and number of devices (Figure 14). Since, the solving time depends not only on the network topology but also on the monitoring load (Y, see §7.2), we need to recompute this graph whenever the monitoring load changes significantly. We use the following procedure to quickly re-

compute the solving time vs number of devices graph: we divide the network topology into clusters of different sizes. Then we run the Optimizer for a sample of these clusters which have different sizes, and we effectively obtain solving time as a function of number of nodes (cluster size). Figure 14 shows this in action.
Figure 14: Determining cluster sizes — X-axis represents the number of nodes in a cluster, and Y-axis denotes maximum time to solve *just one* cluster (averaged over 5 clusters of the same size in the topology)

B Performance Profiler Details

Non-uniform Memory Access Pattern. Sketches such as UnivMon which have multiple control paths can result in non-uniform access of the working memory set even if the traffic is uniform. There are at least the following two ways to handle such cases: (1) estimating *effective memory size* that is accessed uniformly, (2) estimating *hit rates* to different levels of memory hierarchy. In what follows provide some background on the operations of the UnivMon sketch and then describe these two approaches in more detail. In our implementation, we use the first approach to incorporate UnivMon.

- *Background on UnivMon sketch.* UnivMon is an ensemble of Count Sketches and consists of multiple levels. Each level maintains a Count Sketch. On every packet, a hash function is computed to decide a level and the corresponding level is updated.[3] The level is decided by the count of leading non-zero bits of the hash output. Each bit of the hash output is equally likely to be zero or one. Due to this, subsequent levels are accessed with exponentially decreasing probability, i.e.,

$$P(i) = \begin{cases} 2^{-i} & \text{if } i < k \\ 2^{-(k-1)} & \text{if } i = k \end{cases} \quad (2)$$

where P is the probability of accessing level i, and k is the total number of levels.

- *Effective memory size accessed uniformly.* As shown in Figure 15, we study the variation of time per packet

[3]Note, we use an optimized version of UnivMon described in [76] which is slightly different from the original UnivMon paper [11]
Figure 15: Dealing with non-uniform memory access patterns UnivMon effectively behaves as having at most 4 levels from the perspective of memory size accessed uniformly. The black dotted lines show the time per packet for a hypothetical sketch with $2 * 6 + 1 = 13$ hashes per packet and 6 memory accesses where the accesses are made uniformly. (The 13 hashes are: 2 hashes per row for a Count Sketch and one hash to decide level.)

for the UnivMon sketch on a CPU as we vary its levels. We observe that UnivMon effectively behaves as if it had at most four levels, all of which are accessed uniformly. In the Optimizer, this corresponds to using T(Effective uniformly accessed memory) instead of T(Total memory) (T was defined in §4). For other sketches with complex control paths, a similar strategy can be used.

- *Estimation of hit rates.* This is a more theoretical approach, but has similar results as above method. We assume that the caching mechanism on the device being profiled honors temporal locality to decide which items to keep cached, i.e., we can assume that the probability that an item is kept in the cache is proportional to its access frequency. Using this, we estimate the likelihood that an item is cached. Then using (1) the likelihood that an item is accessed (access frequency) and (2) the likelihood that the item is in cache; we estimate the expected inverse throughput of memory accesses leveraging inverse throughputs to different cache levels. Inverse throughputs to cache levels are estimated using the ridges in the memory benchmark of the Profiler (Figure 4a). In what follows, we illustrate application of this process on UnivMon with a toy device.

Let's assume the UnivMon sketch has k levels and each level has consumes x bytes. For simplicity, let's assume the toy device has two cache levels: L1 and L2, with sizes x and $(k-1)x$ bytes respectively. Recall that, the ith level of UnivMon is accessed with probability $P(i)$. Through the locality principle, we expect that $P(i)$ fraction of level i would be present in L1 cache and $1 - P(i)$ in L2 cache. Then the probability that an access goes to

L1 cache is:

$$P_{L1} = \sum_{i=1}^{k} P_1 * P_2 \qquad (3)$$

$$= P(i) * P(i)$$

$$= \left(\sum_{i=1}^{k-1} 2^{-2i} \right) + 2^{-2(k-1)}$$

$$= \frac{1}{4} \left(1 + \left(\sum_{i=2}^{k-1} 2^{-2(i-1)} \right) + 2^{-2(k-2)} \right)$$

$$\approx \frac{1}{4}$$

$$\text{and, } P_{L2} = 1 - P_{L1} \approx \frac{3}{4}$$

where P_1 is the probability that level i of the sketch is accessed, P_2 is the probability that the accessed data is in L1 cache given that some data in level i is accessed, and P_{L2} is the probability that L2 is accessed. Then, the expected inverse throughput of memory accesses would be $P_{L1} * IT(L1) + P_{L2} * IT(L2)$, where $IT(.)$ is the inverse throughput to the corresponding cache level.

For the same toy device, we do a similar analysis for a sketch with size $4x$ bytes, where the memory accesses are made uniformly. Then random x bytes of the sketch would be in L1 and remaining $3x$ in L2. $P_{L1} = $ probability that an element in L1 cache is accessed $= x/4x$. Hence, expected inverse throughput for memory accesses is $0.25 * IT(L1) + 0.75 * IT(L2)$. We see that the access probabilities (hit rates) and the expected inverse memory access throughput for this sketch is roughly equal for Univ-Mon example above, consistent with the empirical approach.

Such expressions for expected memory access time can be accommodated as constraints in the MIP formulation of the Optimizer albeit with increased solving time due to additional non-linear constraints. We leave exploration of this for future work.

Non-uniform Traffic. In the Optimizer and Profiler, we study performance and allocate resources for worst case (uniform) traffic. This is because the traffic distributions may not be known apriori, or one might want to allocate resources to handle adversarial cases. However, if this is not true, one could adapt our work to use the known traffic distribution to estimate hit rates to different cache levels similar to that described for accommodating sketches with non-uniform memory access patterns above.

Impact of profiling errors on Optimizer. We observe that most of the errors in profiling occur when sketches use a large amount of DRAM (or off-chip memory) on the devices. We seek to study what difference, such errors can create to the Optimizer's output. In the Optimizer's output, we identify devices which use a non-zero amount of DRAM, and whose resource allocation would change if the device profiles are off

by 10%. We show in Figure 16 how many more resources would be needed for a Clos topology with 16 pods as we vary the sketch load (Y) (defined in §7.2). We observe that consistently less than 5% of devices satisfy the above conditions. Hence, the Optimizer's allocation would be off only for these 5% of devices. To illustrate this, let's assume all 5% devices are CPUs, each of these devices would need one more core if the profiles under-predict time per packet. Our savings suggest 0.5(50%) to 1(100%) cores saved per server. The errors are significantly smaller compared to the demonstrated savings. Note, that the profiles still are assumed to be accurate for the cases when sketches don't occupy DRAM.
Figure 16: Impact of profiling errors The Y-axis shows the percentage of devices which use DRAM and whose resource allocation would change if the profiles are off by 10%.

Supplementary Evaluation. In addition to the Profiler evaluation for Count-Min sketches on CPUs, shown in Figure 6, we have also have the the detailed results for the other sketches including Count Sketch and UnivMon on CPU, SmartNIC, and FPGA shown in Figures 17, 18, and 19.

C Optimizer Details

Device profiles. Here we give an example of what the device profile ($dtime(.)$) looks like. The following shows the device profile for SoC SmartNIC.

$$dtime = max \left(\frac{k_1 + u_h \cdot h}{c}, k_2 + u_m \cdot T(m) \right) \qquad (4)$$

$$= max(dtime_h, k_2 + u_m \cdot T(m))$$

$$= max(dtime_h, k_2 + u_m \cdot t_{mem})$$

$$dtime_h \cdot c = k_1 + u_h \cdot h \qquad (5)$$

$$t_{mem} = T(m) \qquad (6)$$

where u_h, u_m, and m (as defined in Section 4) are expressed as linear functions of sketch placement decision variables and c is a decision variable corresponding to the number of micro-engines. $T(.)$ is a non-linear function modelled using piecewise-linear constraints and the product terms: $u_m \cdot t_{mem}$, $dtime_h \cdot c$ are modelled using bi-linear constraints. These functions show a decoupled system with sketching done on the forwarding critical path with fraction of parallelizable execution $f \approx 1$.

Tweaking MI-BLP. We show how the MI-BLP formulation can be adapted to support other objectives/goals. We show in Equation 7, how a user can minimize performance overhead as an objective and subject to this minimum, again minimize resource overhead. This is done using hierarchical objectives [77].

Abstract

Sketching algorithms or sketches enable accurate network measurement results with low resource footprints. While emerging programmable switches are an attractive target to get these benefits, current implementations of sketches are either inefficient and/or infeasible on hardware. Our contributions in the paper are: (1) systematically analyzing the resource bottlenecks of existing sketch implementations in hardware; (2) identifying practical and correct-by-construction optimization techniques to tackle the identified bottlenecks; and (3) designing an easy-to-use library called *SketchLib* to help developers efficiently implement their sketch algorithms in switch hardware to benefit from these resource optimizations. Our evaluation on state-of-the-art sketches demonstrates that SketchLib reduces the hardware resource footprint up to 96% without impacting fidelity.

1 Introduction

The ability to monitor network traffic is necessary for various network management tasks such as traffic engineering, anomaly detection, load balancing, and resource provisioning [10, 13, 27, 29, 43, 45, 54]. In this respect, recent developments in programmable switches and attendant languages [9, 14] make it possible to support richer fine-grained and real-time monitoring capabilities.

With this network programmability, sketch-based monitoring has emerged as a promising alternative to traditional sampling-based techniques [19, 49]. At a high-level, sketch algorithms consist of updating multiple counter arrays with a series of independent *hash function calls* and *counter updates*. Sketch-based approaches have been developed to support a broad spectrum of measurement tasks with provable resource-accuracy trade-offs, including heavy-hitter detection or quantile estimation (e.g., [17, 21]), general estimation capabilities (e.g., UnivMon [41]), and more expressive multidimensional analytics (e.g., R-HHH [12]).

While prior efforts have demonstrated the feasibility of expressing sketches using these language APIs [32, 41, 46, 53], implementing sketches efficiently in hardware remains an open challenge. For example, off-the-shelf sketch implementations often cannot run with the desired accuracy levels due to insufficient hardware resources (see §3). Indeed, some proposed sketches (e.g., [41]) are infeasible as implemented, or even if they are feasible, consume significant resources.

Even if more hardware resources may become available, so too do operators' demands of in-switch applications, and the resources consumed by sketches will be unavailable for other switch functions. Thus, it is essential to explore if, and how, we can efficiently realize sketch-based telemetry on programmable switches. This is the central question that this paper tackles. Specifically, we focus on programmable hardware switches based on the Reconfigurable Match-Action Tables (RMT) paradigm [1].

We identify and analyze four key resource bottlenecks for realizing sketches on RMT switch hardware:

- *Hash calls:* Sketches make a number of counter updates based on independent hash functions, requiring a large number of hash calls in hardware.
- *Memory accesses:* Sketches need to access on-chip memory (e.g., SRAM) for counter updates, but the number of memory accesses per packet is limited in hardware.
- *Pipeline stages:* Some sketches need to select a subset of counter arrays for counter updates [23, 37, 41]. However, implementing this naively can cause a long chain of sequential computation dependencies which stresses the limited number of switch pipeline stages.
- *Resources for tracking heavy flowkeys:* Some sketches need to keep track of the flowkeys identifying the heavy hitters (e.g., 5-tuple, source IP, or destination IP) [12, 17, 21, 36, 41]. Common structures such as priority queues or heaps used in software are not supported on programmable switches and existing solutions entail undesirable tradeoffs between miss rate, data plane memory, and control plane bandwidth.

Having identified these bottlenecks, our contribution is a careful synthesis of known and novel optimizations into a practical library for enabling efficient sketch implemen-

tations atop the RMT architecture. While some of these build on prior work in optimizing sketching for other targets such as software switches, FPGAs, and embedded platforms [40, 51, 52, 55], our main contribution is in realizing feasible and effective optimizations based on our bottleneck analysis and translating them into the switch hardware setting. For example, to reduce the number of hash calls, we identify opportunities to consolidate and reuse hash results across multiple counter updates [24, 35]. Similarly, we identify an opportunity to reduce the pipeline stages by eliminating code dependencies based on longest prefix matching using TCAM [55]. We reduce the memory accesses by refactoring sketch algorithms and removing unnecessary memory accesses. We also develop practical flowkey tracking mechanisms that are feasible in hardware. Note that all optimizations preserve correctness while reducing the resource footprint.

To make it easy for sketch developers to benefit from these optimizations with minimal effort, we implement *Sketch-Lib*, an easy-to-use API using the P4 language [14]. These optimizations can be applied to a broad spectrum of classical sketches (e.g., [17, 21, 36]) and recent innovations (e.g., [12, 41]). We qualitatively evaluate the suitability of SketchLib for 19 published sketches and observe that 15 of them can be expressed and can benefit from one or more of our optimizations. We acknowledge that not all optimizations are applicable for every sketch and we envision sketch developers using our API to adopt the relevant optimizations.

We quantitatively evaluate the utility of SketchLib in improving 7 of the 15 applicable sketches covering a diverse set of target telemetry tasks: Count Sketch (CS) [17], PCSA [25], MRAC [37], Multi-resolution Bitmap [23], Hierarchical Heavy Hitters [12], and UnivMon [41]. Our evaluation using a range of packet traces empirically confirms that our optimizations provide similar accuracy ($\leq 1.9\%$) with substantially (up to 96%) reduced resource usage. Furthermore, some complex sketches (e.g., UnivMon) that were previously infeasible on current hardware become feasible.

Contributions and Roadmap. To summarize, we make the following contributions:

- **Bottleneck Analysis (§3):** We identified four key resource bottlenecks for sketch implementations on the hardware programmable switch.
- **Optimizations (§4):** We identify and synthesize practical correctness-preserving optimizations to address the bottlenecks for sketches on switch hardware.
- **API Implementation (§5):** We design a convenient API to make our optimizations easy to use for developers who implement sketches on RMT programmable switches.[1] We verified significant resource benefits on a broad range of sketching algorithms.

---

2 Background

In this section, we start by providing some background on sketching algorithms and programmable switch architecture. We then describe how the sketch code is mapped onto the hardware resources.

2.1 Background on Sketches

Sketching algorithms or *sketches* are randomized approximation algorithms that are designed to compute different observed statistics on a given data stream during every measurement time interval called *epoch*. In network monitoring, prior work has shown that sketches (e.g., [12,17,21,32,40–42, 46,53]) offer better resource-accuracy tradeoffs relative to traditional techniques that rely on sampling (e.g., NetFlow [19]). Our focus in this paper is not to develop new sketches but to enable efficient sketch realizations on programmable switches. To better understand the different resource requirements of sketches, we classify prior sketching work into two categories:

1. Single-level sketches: As a canonical example, consider the *count sketch* (CS) [17] for heavy hitter detection shown in Fig. 1. A single-level sketch such as Count Sketch maintains a 2D-array of counters: R independent counter arrays with size of W; i.e., $R \times W$ memory counters. As each packet arrives, we extract a flowkey from the packet (e.g., srcIP, IP 5-tuple). On this key, we compute two independent hash functions c_i and s_i, corresponding for each row i. c_i is used to select a specific column and s_i is a 1-bit hash used to determine either to increase or decrease the counter.
Figure 3: RMT switch architecture.

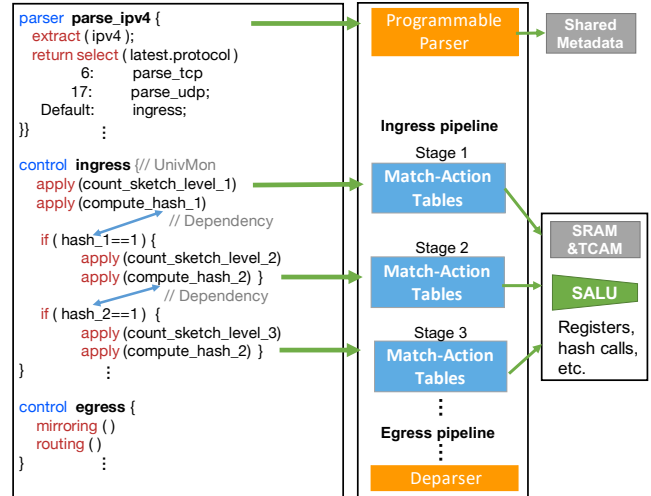
Figure 4: Mapping P4 code to switch resources.

The total number of hash computations is $2R$. Count Sketch requires additional memory space for storing heavy flowkeys whose estimated flow counts are above a threshold. Other single-level sketches requiring a 2D-array include the count-min sketch (CMS) [21], k-ary (Kary) sketch [36]. Some single-level sketches like HyperLogLog (HLL) [26] only need a 1D array data structure.

2. Multi-level sketches: Conceptually, these consist of multiple single-level sketches to enable richer queries. For instance, R-HHH and UnivMon can use multiple count sketches, called levels (e.g., L levels of $R \times W$ counters). R-HHH supports detection of hierarchical heavy hitters, which detects heavy hitters based on different lengths of IP prefixes and Univ-Mon provides more general estimation capabilities. Other sketches like PCSA, MRAC, and multi resolution bitmap (MRB) [23,25,37] use multiple 1D-array single-level sketches. Multi-level sketches typically select a subset of counter arrays to issue counter updates for a given flowkey. For instance, as shown in Fig. 2a, R-HHH randomly selects one level of count sketch using a level-specific key (e.g., IP prefix) to update per packet. In contrast, UnivMon uses an additional sampling stage using hash functions that return 0 or 1 to select levels for update, as shown in Fig. 2b.

2.2 Programmable Switch Hardware

Our focus in this paper is programmable switch hardware based on the Reconfigurable Match-Action Tables (RMT) paradigm [15]. A canonical commercial realization of this architecture is the Intel Tofino switch chip [1]. Based on public documentation and conversations with vendors, we believe that while other programmable switches (e.g., Broadcom Trident [2]) may have different hardware resource allocation strategies, the architectural bottlenecks for sketches are likely similar. We leave it as future work to extend SketchLib to other hardware targets.

Hardware architecture. RMT-based programmable switches have a pipeline of reconfigurable match-action tables in the data plane, as shown in Fig. 3. There are constraints in packet processing pipeline to meet the line-rate processing requirement. For example, at each stage, a packet can access a limited amount of compute and memory resources. Each stage has an identical design with the same types of resources. To provide flexible match-action operations, each stage has a *match table* that matches packet


headers to specific values followed by an action unit that executes a set of simple instructions, depending on the output of the matching unit.

Key hardware resources. We now briefly describe the key hardware resources available in each pipeline stage. First, there are a number of hardware *hash function calls* (hash calls) per pipeline stage. They are used to compute hash functions (e.g., CRC with user-defined polynomials) over packet header fields or metadata to support operations such as load balancing and table lookups. Each pipeline stage also has a fixed amount of SRAM that can be used to maintain state, for example counter arrays. *Stateful ALUs* (SALUs) are hardware resources that allow one read and one write operation to the stateful object in SRAM. Each SALU can be used for counter update operations such as counter increment or decrement. Finally, each pipeline stage is also equipped with some amount of *ternary content-addressable memory* (TCAM) that can be used for wildcard matches over header fields. Overall, the amount of these resources is fixed at hardware design time, and it is limited. For example, a commercial programmable switch today is equipped with (at most) 10 SALUs, 10 hash calls, 10 MBs of SRAM and TCAM per pipeline stage with a total of 12 pipeline stages [15,43,56].[2]

The data plane can interact with the switch control plane for additional processing. However, the switch control plane is not designed for real-time processing, e.g., the bandwidth to the control plane is limited and the response time is high. So it is only useful for infrequent operations.

2.3 P4 Programming and Compilation

Programs for RMT switches are written in the P4 language [14] as illustrated in Fig. 4. At a high-level, a P4 program consists of the following components. First, a packet parser parses the header fields of each packet and stores the extracted fields into metadata. Second, a series of match-action

---

[2]The other absolute resource numbers are proprietary.

Figure 5: UnivMon entropy estimation error for different configurations. Dotted red line indicates target accuracy.

operations are executed based on the *match-action* abstraction, e.g., matching a specific header field and update a register as an action. The action is specified by special functions that map operations to hardware resources, e.g., functions for hashing and accessing memory. Finally, the P4 program defines the packet forwarding behaviors, e.g., routing a packet to an egress port, recirculating it in the pipeline, or forwarding it to the switch control plane.

The P4 compiler maps the P4 program into a static pipeline realization. The compiler analyzes the *dependencies* between operations in the P4 program, to map the program on to the pipeline stages. For instance, given the code snippet in Fig. 4, the resolution of each `if`-clause depends on the previous hash result. Because of this dependency, two consecutive `if`-clauses cannot run in parallel, so the compiler has to map them to different pipeline stages in order for them to run sequentially. If a mapping of a whole program is possible considering hardware constraints, packets are guaranteed to be processed at line rate; otherwise compilation fails. Note that vendor-specific compiler backends are typically proprietary.

3   Bottleneck Analysis

In this section, we consider three exemplar sketches (single-level: count sketch; multi-level: R-HHH and UnivMon) to quantify the resource bottlenecks. We implement them in P4 based on the logic described in prior work [17, 23, 25, 26, 37, 41] similar to the structure presented in Fig. 2.

3.1   Methodology and Setup

Configuring sketches. Running sketches entails picking parameters (e.g., the count (R) and size (W) of counter arrays) to trade-off the accuracy vs. resource use. We envision an operator configuring the sketches with some target accuracy goal, e.g., the median error should be less than 5%. Operators can use trace-driven analysis to pick reasonable operating regimes for these parameters.

As an example, Fig. 5 illustrates this trade-off for entropy estimation using UnivMon. The figure shows the estimation accuracy using an hour-long inter-ISP packet trace captured on a OC-192 link [7] with different parameters R and W for count sketches and $L = 16$ levels. We see that the error decreases as we increase the number of rows (R) and width (W)

for count sketches. Naturally, the higher accuracy configurations incur more hardware resources. For our bottleneck analysis, we target an accuracy of under 5% median error (dotted red line in Fig. 5), which we achieve with minimal resource use with the configuration $R = 3$ and $W = 2048$. We repeat the analysis for count sketch and R-HHH and consider a similar operating regime for these sketches as well.

Estimating resource footprint. For a given set of sketch parameters, the most direct way to measure the required hardware resources is to compile the code and run it on the hardware. However, this limits our analysis to currently available platforms. In order to support "what if" analysis for hardware with different resources (e.g., more pipeline stages), we extended an existing open source tool for mapping P4 programs to the RMT hardware, which we will refer to as RMT resource mapper [34]. Specifically, we address three issues to extend RMT resource mapper for our analysis:

- *Inputs:* The input to Tofino compiler is P4-16 code with some hardware-specific primitives whereas RMT resource mapper accepts only P4-14 code [8]. Thus, we first convert our P4-16 code into equivalent P4-14 code. Then, we convert Tofino-specific primitives to equivalent ones specified in the language specification. For instance, we replace Tofino-specific primitives for accessing registers with *register_read* and *register_write*.

- *Resources:* First, RMT resource mapper does not model hash calls and SALUs in their original design. Thus, we extend RMT resource mapper to model hash calls and SALUs and added the corresponding optimization constraints for assignment of these new resources. Second, we observed that RMT resource mapper assigns memory even for tables without any entries and action data. To fix this disconnect, we decouple the memory/table assignment.

- *Objective:* RMT resource mapper supports different optimization objectives: minimizing latency, power, or pipeline stages. The objective of minimizing pipeline stages is the most suitable because it gives resource mappings that are closest to those generated by the Tofino compiler.

With these fixes in place, we validate our extensions by comparing the resource usages between RMT resource mapper and Tofino compiler for a wide range of sketches and configurations, for the cases that are feasible on current hardware. Based on the measurement results, we conclude that our modified RMT resource mapper is a good proxy of Tofino compiler as it captures the relevant resource constraints, and its resource allocation results are close to that of Tofino compiler (see Appendix A for more details).

3.2   Identified Bottlenecks

Using the RMT resource mapper, we measure the usage of each type of resources based on the output of the compiler for three sketches: Count Sketch, R-HHH, and UnivMon. For the purpose of bottleneck analysis, we use a base configuration
(a) Hash Calls

(b) SALUs

(c) Flowkey Space

(d) Pipeline Stages

Figure 6: Resource bottlenecks for sketch implementations.

of: $W = 2048$, $R = 3$, and $L = 16$ for UnivMon and $L = 25$ for R-HHH [12], which provides an error of up to 15% when processing packets from an inter-ISP packet trace [7]. We choose the value for L from the original papers [12, 41].

Fig. 6 illustrates how the use of four bottleneck resources depends on key sketch parameters. While the amount of available hardware resources can differ across hardware vendors and versions, we see that resource usage increases rapidly as we need more counters to meet higher accuracy requirements. While we cannot report exact resource usages due to proprietary reasons, we note that UnivMon and R-HHH are infeasible today on the hardware for many configurations. Perhaps more importantly, switches must also support tasks other than sketch-based telemetry (e.g., [33, 43]). Thus, it is critical to reduce the resource footprint of the sketches to ensure they can co-exist with other switch functions.

B1. Hash calls: Recall that count sketch needs $2R$ hash calls per packet (§2.1), matching the results in Fig. 6a. UnivMon and R-HHH execute one count sketch per level L. As a result, R-HHH needs $L \cdot 2R$ hash calls. UnivMon needs to compute an additional L 1-bit hash calls in its sampling stage, adding up to $L \cdot (2R + 1)$ hash calls.

At first glance, it may seem that the number of hash calls is not a bottleneck as these are called on demand per packet. While this is true in a software setting, where only the required calls are performed on demand, hashing on hardware is different. On a hardware switch, all hash calls appearing in the code need to be *pre-allocated* since execution at line rate must be guaranteed for all possible execution paths. This increases resource requirements, even if hash calls need not be executed. For example, even though UnivMon and R-HHH (Fig. 2) may not update all levels of count sketches for all packets, all hash resources must be pre-allocated.

B2. Memory accesses: Count Sketch maintains R counter arrays (§2.1) and for each row it must read one counter from memory and update its value. This means that count sketch needs R counter updates per packet, requiring R Stateful ALUs (SALUs) as shown in Fig. 6b. When the compiler compiles

the P4 code of UnivMon and R-HHH in Fig. 2, it allocates separate memory regions and SALUs for each level of count sketches, thus SALU requirements are proportional to the number of levels L. Since we need R memory processes per packet for the count sketch at each level, we need a total $L \cdot R$ SALUs for R-HHH and UnivMon. This makes memory access hardware (SALU) a bottleneck (Fig. 6b). Similar to hash resources, SALUs need to be *pre-allocated* at compile time, even if they may remain unused.

B3. Resources for tracking heavy flowkeys: Many sketches need to track heavy flowkeys to enable downstream analytics tasks. Typically, these sketches store heavy flowkeys in a separate data structure (e.g., heap or priority queue) [17, 41].

In practice, however, the exact details of if/how this can be realized on switch hardware are unclear. Specifically, a heap or priority queue, while feasible in software switches is too complex to be implemented on the programmable hardware switch. Alternatively, the data plane can relay all flowkeys to the switch control processor or record all flowkeys in the data plane. However, these are not feasible; e.g., bandwidth between the data plane and the control plane is limited, and data plane memory is also limited. Some sketch constructions store heavy flowkeys together with the counters [11, 32, 46]. However, these are infeasible at line-rate on today's RMT switches.[3]

To reduce the memory use, prior work proposed an optimized baseline—when a packet arrives, it checks whether the frequency of a flowkey has exceeded the threshold by querying the sketch counter, and if so, it reports the key to the control plane [33, 39, 41]. Unfortunately, this still has a problem as "heavy" flowkeys may be reported redundantly every time a packet arrives and needs more control plane bandwidth. To avoid duplicate reporting to the control plane, we could use a Bloom filter to check if a heavy key has already been reported [33]. However, we need to configure the Bloom filter (i.e., bitmap size and number of hash functions) to have really low false positives since a false positive in the Bloom filter for the duplicate check is a potential miss of a heavy flowkey. Fig. 6c confirms this trade-off; we can configure the Bloom filter depending on the target miss rate and we find the memory footprint is correspondingly higher (We use 3 hash functions for Fig. 6c). Using a Bloom filter might be a valid approach if we allow some missing heavy flowkeys, we argue a design that targets a zero miss rate is more desirable.

We implement four possible strawman solutions to report heavy flowkeys and run microbenchmarks on a Tofino hardware switch to understand a trade-off between the accuracy and the resource consumption. Table 1 summarizes our analysis and shows that we have an undesirable trade-off between the miss rate of heavy flowkeys, data plane resources (mem-

---

[3]Specifically, HashPipe [46] cannot be directly implemented on RMT architecture due to complex memory access patterns (see [11] for more details). Precision [11] requires recirculation, which means some packets must go through entire pipeline again.

	Miss rate	CP bandwidth	DP resource
Recored every key in the DP	Zero	Low	Infeasible
Report every key to the CP	Zero	Infeasible	Low
Report heavy keys to the CP	Zero	Infeasible	Low
Report non-duplicate heavy keys	Low	Low	High

Table 1: Strawman solutions for tracking heavy flowkeys (CP: control plane, DP: data plane).

ory for keys and hash calls for Bloom filters), and the control plane bandwidth (for reporting keys).

B4. Pipeline stages: So far we have implicitly assumed that the switch has a single pool of resources on the switch (i.e., SRAM/TCAM, SALUs, and hash calls) that can be allocated to the sketch operations. In reality, the resources are partitioned across the pipeline stages. This impacts resource use in two ways. First, before an operation can be assigned to a stage, all required resources need to be available on that stage. If that is not the case, it needs to be moved to the next stage. Second, if there is a dependency between two operations, e.g., $O_1 \rightarrow O_2$ in the code, then O_2 must be placed on a later stage than O_1, even if there are unused resources available on stages earlier in the pipeline. For example, the sequential if clauses used by UnivMon (Fig. 4) create sequential dependencies between the *if* clauses.

This means that, depending on resources required by operations and dependencies between them, the compiler will only be able to use a subset of the resources on the switch. To account for this, we consider pipeline stages as a separate resource. Fig. 6d shows the number of pipeline stages needed as a function of level L if we respect this architectural constraint. We see that UnivMon requires similar or more pipeline stages than R-HHH with same configuration parameters and the gap is increasing as the number of levels increases. This is a direct result of the sequential dependencies in UnivMon. The number of pipeline stages used is measured by running the RMT resource mapper.

4 Optimizations

Next, we present a series of optimizations to address the resource bottlenecks we identified earlier. For each optimization, we discuss the key idea, before discussing the correctness and applicability constraints. Some of these optimizations (e.g., O1, O3, O4) have appeared in earlier theoretical efforts and demonstrated in other settings (e.g., FPGA, software switch). Our contribution here is translating these ideas to hardware switches. Others (O2, O5, O6) are novel to the best of our knowledge. As summarized in Table 2, our optimizations can be applied to a broad spectrum of published sketches for telemetry and benefit 15 out of the 19 sketches listed. Some sketches that are outside our scope cannot be supported as they either use: (1) processing logic that is infeasible in hardware (i.e., Hashpipe); (2) counter data structures different

Sketch Type	Sketch Name	Feasible on HW?	Applicability of SketchLib
Frequency Estimation / Heavy Hitters	Count-Min [21]	Yes	O6
	Count Sketch [17]	Yes	O1, O6
	MRAC [37]	Yes	O3, O5
	Hashpipe [46]	No	N/A, due to infeasible logic
	Precision [11]	Yes	No, uses packet recirculation
Hierarchical Heavy Hitters	RHHH [12]	Yes	O1, O2, O5, O6
	HHH [20]	Yes	O1, O6
Cardinality	PCSA [25]	Yes	O3, O5
	MRB [23]	Yes	O3, O5
	LogLog [22]	Yes	O3
	HyperLogLog [26]	Yes	O3
Entropy	EntropySketch [38]	Yes	O1
Change Detection	K-ary [36]	Yes	O1, O2, O6
Super Spreaders	SpreadSketch	Yes	O3, O5
	BeauCoup [18]	Yes	No, non-counter based sketch
General	UnivMon [41]	Yes	O1, O2, O3, O4, O5, O6
	FCM [47]	Yes	O6
	SketchLearn [32]	Yes	O2
	ElasticSketch [53]	Yes	Not applicable

Table 2: Applicability of SketchLib on existing sketches.

from sketches (i.e., BeauCoup); or (3) complex processing patterns such as packet recirculation (i.e., Precision).

4.1 Optimizing Hash Calls

Both single- and multi-level sketches need to compute multiple hash functions, resulting in high hash call usage in the hardware pipeline. We describe two optimizations: consolidating short hash calls and reusing hash calls.

Optimization 1. Consolidate many short hash calls. We observe that many hash calls only need short-length (e.g., 1-bit) hash results. For instance, count sketch (Fig. 1) computes a series of 1 bit hash calls, s_1 to s_R. Similarly, UnivMon (Fig. 2 (b)) computes h_1 to h_L. We can reduce the number of hash calls by consolidating many short hash calls, as long as the inputs to the hash calls are the same.

Consider a count sketch with $R \times W = 3 \times 512$ counters. Per row, we need two hash results: a 9-bit (i.e., $\log_2 512 = 9$) hash to index into the counter array and a 1-bit hash for the "sign" of the counter. Instead of using $3 \cdot 2 = 6$ hash calls, we can instead use one hash call that returns a 30-bit result to provide the 6 hash calls as in Fig. 7. Note that splitting a long hash result only needs simple hardware shift and bit mask operations. R-HHH and UnivMon are also benefited as they use multiple count sketches. Further, UnivMon uses many 1-bit hash calls in its sampling stage.

Correctness and applicability: For this optimization to be valid, the split short-bit hash results from the longer hash result must use the same flowkey as the input and, if required by the sketching algorithm, be pairwise independent [17]. Independence is achieved by randomly picking (different) seeds for hash calls in practice [12, 41, 53]. Theoretical anal-
Figure 7: Optimization 1 reduces hash calls for count sketch.

Flowkey	Seed	Additional Condition	Opt
same	diff.	Sum of hash bit length is less than max capacity	O1
same	same	-	O2
diff.	same	One level of hash calls is executed	O2
diff.	diff.	-	-

Table 3: Conditions for optimization 1 and optimization 2.

ysis in other contexts [24, 35] shows that using different bits from the same hash call can also provide independence. Empirically, recent work [51] shows no accuracy loss for Univmon and our results (§6) confirm this with other sketches listed in Table 5. In addition, hash calls need to be short so that the sum of hash bit length is less than the length of one call (e.g., 32 bits). Fortunately, many single- and multi-level sketches [12, 17, 23, 25, 26, 37, 41] satisfy this condition.

Optimization 2: Reuse the hash calls across levels for multi-level sketches. Our second insight is that we can reuse the hash calls if there are no independence requirements across them ; i.e., they can use the same seed. Although hash independence is usually required across different counter arrays within a single level sketch, it is not required *across* levels [16]. Thus, we can use the *same* hash seed cross different levels for multi-level sketches.

Specifically, the original implementations of R-HHH and UnivMon (see Fig. 2) use a *different* hash seed in each of the *CS_level_i* count sketch executions. We can modify the code to reuse the same hash seed and reuse hash results when independence is not needed. This optimization reduces the number of hash calls significantly. For example in Fig. 2, R-HHH and UnivMon each have a set of hash calls F_i as $\{f_{i1}, f_{i2}, ... f_{i(2R)}\}$ at each level i of count sketch, resulting in $L \cdot 2R$ hash calls. By simply changing all of F_i to F_1, we reduce hash call usage from $L \cdot 2R$ to $2R$. For R-HHH, the result of F_1 is used to update one selected level of count sketch, and for UnivMon, result of F_1 can be used to update potentially multiple levels per packet.

Correctness and applicability: Reusing seed values across levels does not affect the theoretical independence requirements [16]. We empirically confirm in the evaluation that this optimization achieves similar accuracy (§6.1).

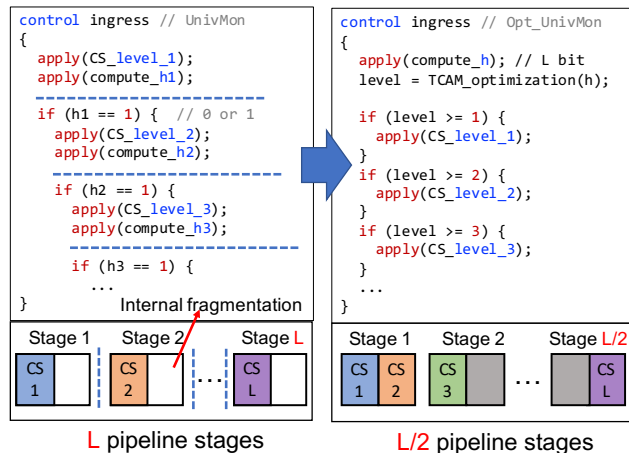
Table 3 summarizes the conditions under which the two hash optimizations are used. Note that for O2, if different levels' hashes have diverse output bit-length requirements, the hash call with the longest output bit-length will be used to supply hash results with various bit lengths. Also we need to make sure that the hash seeds are either the same in the first place or can be set to the same for O2 to apply.


Figure 8: Optimization 3 removes the sequential computation dependency and reduces the usage of pipeline stages.

4.2 Optimizing Pipeline Stages

The sequential `if` clauses are observed in both single and multi-level sketches. This creates sequential compute dependencies and entails high usage of pipeline stages.

Optimization 3: Avoiding the sequential `if` clauses using a longest prefix match. To explain this optimization, we use UnivMon (Fig. 8) as an example. Deciding which levels to be updated for each flowkey creates a logical *dependency* between levels. Specifically, level i+1 needs to be updated only if the value of h_i returns 1 for hash functions $h_i : [n] \rightarrow \{0/1\}$. These L-level dependencies lead to an implementation as Fig. 8-left using sequential `if` clauses with hash values $(h_1, h_2, \ldots, h_L)$.

To address this bottleneck, our insight is that the number of leading 1-bits in $(h_1, h_2, \ldots, h_L)$ represents the sequence of "true" conditions in the `if` clauses. We observe that this is equivalent to the *longest prefix match* (LPM), which can be computed efficiently in hardware. That is, we can compute L hash bits together using a single L bit hash and use LPM to identify which layers need to be updated. This LPM operation is realized via TCAM as shown in Fig. 9. We insert rules with 1- and wildcard bits corresponding to each level and perform LPM to obtain the last level of UnivMon for each flowkey. LPM is relatively cheap—can be done in one pipeline stage using a small amount of TCAM. With this optimization, we can reduce the usage of pipeline stages by half if one count-sketch consumes half of the resources in one pipeline stage (Fig. 8-right).

Correctness and applicability: Our refactored implementation has the same functionality, resulting in the same updates to the sketch arrays. This optimization applies to many single and multi-level sketches that build on the power-of-two choices observation [23, 25, 26, 37, 55].
Figure 9: Replacing the sequential `if` clauses via TCAM.

4.3 Optimizing Memory Accesses

Sketches require memory accesses for their counter updates, leading to high SALU usage. This becomes especially significant for multi-level sketches.

Optimization 4: Refactor multi-level sketches to update one level per packet. We refactor multi-level sketching algorithms and their code to guarantee only one level is updated per flowkey. Recall that UnivMon needs to update one or more levels of count sketch (CS) for each packet with its flowkey. In Fig. 10 (top), a flowkey of packet K_{green} updates three levels, K_{gray} updates two levels, and K_{red} updates all levels of count sketch. Instead, our modified algorithm is guaranteed to update only the "last" level for each packet, as shown in Fig. 10 (bottom). The modified algorithm becomes structurally similar to other multi-level sketches that natively update only one level [12, 23, 25, 37]. As a result, the processing overhead is significantly reduced.

This "update-last-level" idea was also proposed to optimize UnivMon for embedded platforms [52] and software switches [40, 51]. Our contribution here is: (1) to extend this to programmable switches and (2) to generalize the idea to support updating arbitrary levels. Based on the algorithmic design, different multi-level sketches may require different optimization strategies to update a level (e.g., RHHH [12] modifies HHH [20] by randomly selecting a level to update). To implement this optimization, we can insert user-defined ternary rules in TCAM (as O3) to classify packets into different levels in a multi-level sketch.

Correctness and applicability: By construction, our modified algorithm provides equivalent functionality as the original version. As shown on the right side of Fig. 10 with K_{green} flowkey as an example, Levels 1 and 2 do not need to be updated anymore. Level 3 has the estimated flow count for this particular flow with the same or better accuracy since Level 3 only processes a smaller amount of traffic than Levels 1 and 2. Thus, the estimated count of K_{green} from Level 3 can be reused for Levels 1 and 2. This applies to all other flowkeys during the offline estimation in the network control plane.

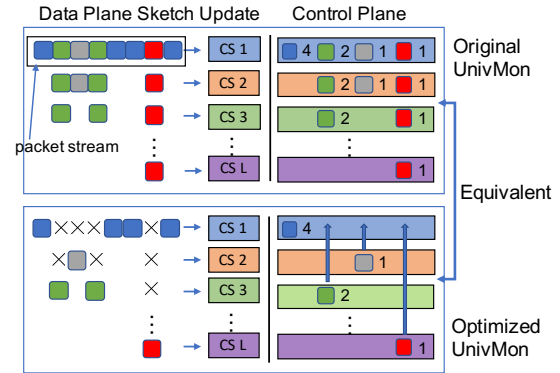
To apply this optimization, a multi-level sketch should meet two conditions: (1) the original algorithm has multiple sketch updates per packet, and (2) it is algorithmically correct to reduce the multi-level updates to one per packet. That said, we acknowledge that there are scenarios where this optimization is not directly applicable. For instance, it is not obvious if/how we can refactor some multi-level sketches such as


Figure 10: UnivMon updates only the last level per packet. CS stands for Count-Sketch.
Figure 11: Optimization 5 removes unnecessary allocated SALUs by rewriting P4 code.

SketchLearn [32] to update only one level per flowkey (if possible). This requires future research.

Optimization 5: Remove unnecessary SALU operations. A multi-level sketch maintains multiple independent levels of sketches. For each counter at each level, the compiler statically allocates an SALU for memory access. This results in high SALU usage, even if only one level needs to be updated per packet; i.e., usage is the same as updating all levels.

We can remove unnecessary SALUs when only one update is needed per packet. The reason why the compiler inefficiently preallocates SALUs for all possible memory accesses is that it is difficult to automatically figure out that only one update is needed at runtime. Our optimization restructures the P4 code to make this explicit for the compiler that only one count sketch update is needed per level. Instead of using separate counter arrays located in different switch memory regions, we consolidate the counter arrays of all levels in a single array located in one region of memory. This is possible because SALU can support random access, thus based on the selected level, we can compute the corresponding index value to access the consolidated register. Fig. 11 illustrates this SALU optimization. This optimization reduces the SALU requirements for multi-level sketches by a factor of L (the number of levels, e.g., 25 for R-HHH [12]).

Correctness and applicability: This technique does not affect accuracy because the modified code has the same functionality as the original version. We can apply the optimization to multi-level sketches that have the property of updating only one level per flowkey. There are many multi-level sketches satisfying this property [12, 23, 25, 37, 41].

Resource Bottlenecks	Optimizations	API
Hash Calls	O1. Consolidate short-bit hash calls	`hash_consolidate_and_split()`

Pipeline Stages	O3. Remove sequential if clauses using TCAM	`tcam_optimization()`
SALUs	O4. Update only one level per flowkey	-
	O5. Rewrite P4 code to reduce memory accesses	`consolidate_update()`
Resources for tracking heavy flowkeys	O6. Use a hash table to remove duplicate flowkeys	`heavy_flowkey_storage()`

Table 4: The relationships among the bottlenecks, optimizations and API calls.

4.4 Optimizing Heavy Flowkey Reporting

Optimization 6: Use a hash table and an exact-match table for checking duplicate flowkeys. As discussed in §3.2 B3, prior efforts [33, 39] use Bloom filters as the duplicate checker but the false positives from the filters will cause misses of heavy flowkeys, unless a very large Bloom filter is used. To improve this tradeoff between miss rate and data plane resource, we use a hash table and an exact-match table to check duplicates. Specifically, the hash table stores heavy flowkeys and detects whether there is a collision. For each heavy flowkey, if it is already stored in the hash table or exact-match table, it will not be reported to the controller; otherwise, it will be inserted to the hash table. But if this flowkey collides with another key in the hash table, then it will be reported to the controller which then inserts this flowkey to the exact-match table to filter future duplicate keys. In this way, we can ensure a zero miss rate on reporting heavy flowkeys.

Correctness and applicability: This optimization ensures a zero miss rate of heavy flowkeys because when collisions happen in the hash table, the flowkeys are reported to the control plane and inserted to the exact-match table (as a secondary duplicate checker). No unique heavy flowkeys are dropped in this mechanism. Compared to Bloom filters, this approach adds some additional control plane bandwidth when collisions happen in the hash table. As we evaluate in §6.5, this added bandwidth is small (e.g., 2% increase). This optimization can be applied to both single- and multi-level sketches requiring heavy flowkey tracking [12, 17, 41].

5 SketchLib API

In this section, we present our P4 API for helping sketch developers to use our optimizations. For each API call, we show the implementation for the macro and how the macro is used. SketchLib API supports both P4-14 and P4-16 [6]. Table 4 maps the optimizations to the API calls.

`hash_consolidate_and_split(Key,Seed,List(BitLen),BL_sum,List(Mask))`[4] reduces hash calls by consolidating small bit hash calls (O1). Fig. 12 shows how a sequence of short hash calls is replaced by a macro that uses only a single hash call with length the sum of all

BitLen of the shorter hashes. The resulting hash value is then partitioned in shorter hashes. For P4-14, we split the result using `modify_field_with_shift(dst, src, shift, mask)` primitive (i.e., `dst = (src » shift) & mask`) where `mask` is a series of 1's with `BitLen` as shown. For P4-16, the same principle is applied, but bit slice operation (e.g., `h[BL1:0]`) is used. Note that the macro specifies both the number of short hashes being merged (*List*) and the names of the short hashes, so multiple macros must be defined if O1 is applied multiple times.

```

Figure 12: `hash_consolidate_and_split()`

`select_key_and_hash(List(Key),Level,Seed,BitLen)` implements O2 for the case one of the several hash calls with different `Key` and same `Seed` is selected for execution. Here, we can select the key in advance and use only one hash call to get the result as in Fig. 13. For instance, R-HHH can be optimized by using this API call. The example shown is a single hash call, but if multiple are needed (e.g. sketch with *R* =5 needs 5 hash calls), the number of hash calls can be increased. For the sketches that share the same `Key` and `Seed` (e.g., UnivMon), no separate API call is necessary since the hash value can simply be reused.

```
1: if (V == 1)
2:   h = hash(key1, seed, 3);
3: if (V == 2)
4:   h = hash(key2, seed, 3);
5: if (V == 3)
6:   h = hash(key3, seed, 3);
        ↓
1: select_key_and_hash_3
    (key1, key2, key3, V, seed, 3)
```

```
1: #define select_key_and_hash_3
    (key1, key2, key3, V, Seed, BL)
2: if (V == 1)
3:   k = key1;
4: if (V == 2)
5:   k = key2;
6: if (V == 3)
7:   k = key3;
8: h = hash(k, Seed, BL);
```

Figure 13: `select_key_and_hash()`

`tcam_optimization(Hash_Result)` implements O3 to remove sequential `if` clauses by applying an equivalent a LPM table which uses TCAM to which levels need to be updated. The macro implements the use of the TCAM to look up the level (see Fig. 8).

`consolidate_update(Level,Index)` implements O5 to reduce memory accesses, as illustrated in Fig. 14. `Level`

---

[4]While there is no concept of `List` in P4, we use it to describe the type of parameters conceptually throughout this section. In our API implementations, it is converted to multiple parameters; e.g., `List(BitLen)` → `(BL1, BL2, BL3)` as shown in Fig. 12.

indicates the selected counter array and `Index` references the location for the memory update within the counter array. The API call consolidates counter arrays and computes the new address for the consolidated array. `size` indicates the bit length (e.g., 10) of the width (e.g., 1024).
```
1: if (V == 1)
2:   update_array_1(V, index);
3: if (V == 2)
4:   update_array_2(V, index);
5: if (V == 3)
6:   update_array_3(V, index);
```
⟶
```
1: consolidate_update_3(V, index)

1:#define consolidate_update_3
                        (V, index)
2: n_index = ((V-1)<<(size))+index;
3: update_array_1_to_3(n_index);
```

Figure 14: `consolidate_memory_update()`

`heavy_flowkey_storage(Key,List(Estimate),Threshold)` reduces the memory space for heavy flowkeys (O6). The challenge is checking whether the estimated flow count is above a threshold entirely in the data plane. Specifically, this entails computing the median value based on an estimated flow count from each row and comparing it to the threshold value. However, computing the median is not supported in the data plane. Instead, we leverage the fact that we can check whether the median of a set of values exceeds a threshold without computing the median as follows. We compare all of estimated flow count for all rows, as shown in lines 3-9 in Fig. 15 which is for R = 3 case. Then, the condition (sum (s1, s2, s3) $\geq$ 2) at line 11 is equal to (median(est1, est2, est3) > T).[5] This can be generalized for different Rs. We implement the duplicate filter using a hash table and a exact-match table. If a flowkey collides with an entry in the hash table and the exact-match table does not have an entry for the flowkey, we report it to switch control plane via a PCIe channel. Upon receiving the reported key, the switch control plane CPU adds entries into the exact-match table.

6 Evaluation

In this section, we evaluate the benefits of SketchLib on seven sketches. Across a range of settings, we see that SketchLib can reduce the resource footprint of sketches on switch hardware (up to 96%) while achieving similar accuracy.

6.1 Experimental Setup

Sketches. We implement all 15 sketches in Table 2 using SketchLib and source codes for sketches are available at [6]. Among 15 sketches, we pick seven representative sketches for our evaluation as in Table 5.

Testbed. We evaluate SketchLib on a local testbed with an Edgecore Wedge 100BF Tofino-based programmable switch and a server equipped with dual Intel Xeon Silver 4110 CPUs, 128GB RAM, and a 100Gbps Mellanox CX-4 NIC connected to the switch. We use the P4-16 version of SketchLib with Tofino SDE version of 9.1.1 in our experiments.

---

[5]For Count-Min sketch [21], we can use (sum (s1, s2, s3) $\geq$ 1).

```
01:#define heavy_flowkey_storage_3
                    (Key, Est1, Est2, Est3, T)
02:
03: s1, s2, s3 = 0;
04: if (Est1 > T)
05:   s1 = 1;
06: if (Est2 > T)
07:   s2 = 1;
08: if (Est3 > T)
09:   s3 = 1;
10:
// above threshold test
11: if (s1 + s2 + s3 >= 2) {
12:   if (HT[h(Key)] == empty) { // HashTable
13:     HT[h(Key)] = Key;
14:     send_to_cpu(Key);
15:   } else if(HT[h(Key)] != Key) {
16:     if (!(flowkey in MT)) { // MatchTable
17:       send_to_cpu(Key);
18:     }
19:   }
20: }
```

Figure 15: `heavy_flowkey_storage()`

Traces. We use five CAIDA backbone traces capture at 3/20/14 to 6/19/14 Sanjose, 1/21/16 Chicago, 5/17/18 to 8/16/18 New York City [7]. We split one hour traces into 30 second epochs. Each epoch includes about 12M-23M packets, with 398K distinct source IPs, 280K distinct destination IPs, and 1.6M distinct 5 tuples.

	Level (L)	Row (R)	Width (W)	Space
CS [17]	-	5	4096	80KB
HLL [26]	-	-	2048	8KB
UnivMon [41]	16	5	2048	640KB
R-HHH [12]	25	3	2048	600KB
MRAC [37]	12	-	2048	96KB
MRB [23]	16	-	4096	8KB
PCSA [25]	32	-	20	0.125KB

Table 5: Sketch parameters for evaluation.

Sketch parameters. Table 5 shows the configuration parameters for the sketches. Most sketches use 4 byte counters. The cardinality estimators (e.g., MRB and PCSA) use bitmap thus each counter is 1 bit.

Metrics. Depending on the sketch and the measurement task, we report two error metrics. For each metric, we run the experiment 5 times independently with different hash parameters and report the 25%, 50%, 75% percentiles of the errors. For brevity, we report results using source IP as the flowkey except for R-HHH, noting that the results are qualitatively similar for other types of flowkeys. R-HHH uses (source IP, destination IP) pair as flowkey as presented in the original paper [12].

- Average Relative Error (ARE): $\frac{1}{k}\sum_{i=1}^{k}\frac{|f_i-\hat{f}_i|}{f_i}$, where k means the top k heavy flows. f_i is actual flow count for flow i and $\hat{f}_i$ is the estimated flow count from the sketch. $f_i \geq f_{i+1}$ for any i, thus it is sorted in descending order. We use k=50 for count sketch and R-HHH.

- Relative Error (RE): $\frac{|True-Estimate|}{True}$, where *True* is ground truth value and *Estimate* is estimated value. We use this metric for sketches that estimate cardinality and/or entropy.
Figure 16: Accuracy comparison of sketches between original and optimized sketches across traces. Left: original, Right: optimized.

Figure 17: Resource consumption before/after optimizations.

6.2 Accuracy

We run the accuracy experiment of SketchLib in two ways. First, we show the accuracy is preserved between baseline software implementation and hardware implementation with SketchLib (§6.2.1). Second, we compare the accuracy of the hardware implementations with and without SketchLib (§6.2.2).

6.2.1 Comparison with the Software Baseline

Reporting methodology. We compare the accuracy of the sketch refactored with SketchLib (on hardware) against a baseline software implementation. The baseline software implementation runs sketches on the software. We run experiments over multiple traces with independent runs. After optimizing sketches with SketchLib, we run experiments on Tofino hardware with all five traces. For each one-hour trace, we randomly sample 40 30-second epochs and obtain 5 accuracy numbers per epoch with independent trials. The server replays traces to the switch using tcpreplay at a speed of 800K packets/second. Between epochs, we wait for switch control plane to pull counters and flowkeys from the data plane (see §7).

Result. Fig. 16 empirically validates that SketchLib optimizations achieve similar accuracy. For every trace, the left blue bar represents the software baseline and the right green bar is the hardware reported result with SketchLib applied.[6] Fig. 16a - Fig. 16d shows the accuracy of sketches that need to track heavy flowkeys and the rest show sketches that need

---

[6]We do not show MRAC as the estimation logic for MRAC is not public.

UivMon	Without SketchLib			With SketchLib
Level (L)	8	6	5	16
Row (R)	4	5	6	5
Width (W)	32768	32768	32768	2048
RE (%)	95.4%	98.8%	99.4%	9.5%

Table 6: Relative error in cardinality estimation with and without SketchLib.

to maintain only counter arrays. Fig. 16c and Fig. 16d show the errors of UnivMon for cardinality estimation and entropy estimation. We can visually confirm that the distributions of accuracy before and after optimizations are similar.

6.2.2 Accuracy Improvement with SketchLib

Reporting methodology. We want to compare the best accuracy between with and without SketchLib on the hardware. We use UnivMon for this experiment. To systematically sweep configuration parameters for the best accuracy without SketchLib, we exploit the property of UnivMon. Among three sketch parameters level (L), row (R), and width (W), L is the most critical parameter, thus we pick three highest feasible L. Then we find maximum R and lastly W. Given fixed L, we explored different parameter R other than maximum R but result was similar. We use the simulator with 40 samples of trace1. With SketchLib, we use the same configuration from the original UnivMon paper.

Result. Table 6 shows that all feasible configurations without SketchLib show high error rate more than 95%. On the other hand, UnivMon with SketchLib shows low error rate of 9.5%.

Sketches	Hash Calls (O1/O2)	SALUs	Pipeline Stages
CS	31%/0		9%
HLL	80%/0		86%
UnivMon	44%/47%	90%	65%
RHHH	32%/60%	92%	62%
MRAC	87%/0	91%	68%
MRB	90%/0	93%	76%
PCSA	92%/0	96%	86%

Table 7: Individual resource reductions by optimizations.

6.3 Switch Resource Consumption

Next, we report the resource usage improvements on the identified resource bottlenecks (Table 7). The sketch parameters used are reported in Table 5.

Reporting methodology. We measure resource usages from original implementation using RMT resource mapper and optimized implementation using Tofino compiler to measure resource reductions. To factor out resource reductions for different optimizations in Table 7, we wrote P4 code with individual optimizations applied using SketchLib APIs to measure the resource usages.

Hash calls. Table 7 shows that using O1 to consolidate the 1-bit hash calls is effective for both single and multi-level sketches. For example, the number of hash calls for count sketch is reduced by 31%. R-HHH and UnivMon benefit from O1 as they are composed of multiple count sketches. Further, PCSA, MRAC, MRB and HLL have a series of 1-bit hash calls which O1 improves. For UnivMon and R-HHH, we can apply both O1 and O2 by reusing hash calls across levels to further reduce hash calls by over 90%. We further investigate the sensitivity of the reduction of hash calls vs. sketch parameters in Fig. 17a.[7] Multi-level sketches UnivMon and R-HHH have significant reduction and the resource used is close to single-level count sketch.

Stateful ALUs. O5 applies only to multi-level sketches and reduces SALU usage significantly if there are many levels in the sketch. With 16-32 levels, O5 saves 92% to 96% of the SALUs. We can see in Fig. 17a that O5 reduces SALU of UnivMon and R-HHH significantly across rows.

Counter Memory Space. Interestingly, O5, which we designed to reduce SALU usage, additionally reduces memory space. Investigating this further, we find that original sketch implementations have a memory region fragmentation problem. One counter array is smaller than a block of SRAM, causing additional (unused) memory overhead per each counter array. O5 has the added benefit of consolidating counter arrays and achieve 54%–96% of resource reduction in memory space for multi-level sketches (not shown).

Pipeline stages. The reduction of pipeline stages depends on a combination of factors — hash calls, SALUs, and code dependencies. Table 7 shows reduced pipeline stages from 9% to 86% across sketches. Sketches where O5 applies (HLL, UnivMon, MRAC, MRB, PCSA) have a large reduction because it removes many sequential `if` clauses. Effectively, our

SketchLib UnivMon	2.59%	2.08%	2.21%	2.36%	2.96%

Table 10: Entropy error (RE), FCM vs. SketchLib-optimized UnivMon.

optimization can make the footprint of multi-level sketches agnostic to number of levels (Fig. 17c).

6.4 Comparison with FCM

FCM [47] is a recently published sketch with general capability, and it is feasible on the programmable switch. Thus, we compare FCM against sketches optimized with SketchLib in terms of resource usages and accuracy. Table 8 shows resource utilization comparison between FCM and SketchLib optimized sketches. We use the same configuration from public FCM code [3], and make SketchLib-optimized sketch use similar resources to FCM.

Heavy hitter detection. Table 9 shows the accuracy result of heavy hitter detection. We can see that FCM+topK suffers from a high error rate because of an inefficient mechanism for tracking heavy flowkey (approximate topK implementation of ElasticSketch [53]). Note that if FCM deploys one of our optimizations for tracking heavy flowkeys, FCM+O6 reduces the error rate significantly from 1.41% to 0.01%. We use the simulator with 40 samples of trace1 and report median ARE.

Entropy and cardinality. Table 10 and Table 11 compare entropy and cardinality estimation accuracy between FCM+topK and SketchLib-optimized UnivMon. In the experiments, UnivMon reports top-200 heavy hitters per level. For entropy, UnivMon shows a relatively stable error rate (2∼3%) across workloads, whereas FCM is dependent on workloads and the error rate can go up to 17%. For cardinality, the error rate of UnivMon is moderately increasing [8], whereas FCM suddenly becomes unusable after 5M flows. This is because Linear Counting [50] is used to estimate cardinality in FCM.

6.5 Tracking Heavy Flowkeys

To evaluate the impact of O6, we consider three metrics: miss rate, control plane bandwidth, and data plane memory. We

---

[7]Missing point for R-HHH in Fig. 17 means it is infeasible.

[8]We observe that, when UnivMon reports more heavy hitters per level, the cardinality error rate decreases (e.g., 17.58% in 10M flows with top-1000).

# of flows	500K	1M	5M	10M	30M
FCM+topK	0.004%	0.107%	0.519%	100%	100%
SketchLib UnivMon	21.9%	20.7%	31.7%	39.5%	73.8%

Table 11: Cardinality error (RE), FCM vs. SketchLib-optimized UnivMon.

Resource	UnivMon	With SketchLib UnivMon + NFs (L2, L3, LB, FW)
Pipe. Stage	12	12
SRAM	7.3%	38.6%
TCAM	0.3%	25.0%
SALUs	12.5%	12.5%
Hash Calls	18.1%	18.1%
Hash Bits	4.9%	11.2%

Table 12: Sketches are infeasible without SketchLib. With SketchLib, there are rooms for additional network functions (L2/L3 forwarding, L4 load balancer, and stateful firewall).

compare SketchLib-optimized approach vs. an "optimal" software solution. For this evaluation, we use two sketches (CS, UM) that track "heavy" flowkeys. For each 1-hr trace, we split it into epochs as before, and set a target threshold corresponding to the top 0.2 percentile of flow sizes (The results are independent of the threshold; this is to make the experiment concrete). Across different traces and sketches, SketchLib incurs zero miss rate, and at most 2% increase in control plane bandwidth (due to small number of duplicates), using less than 400KB of data plane memory overall (independent of the threshold, results not shown for brevity). To put this in context, a Bloom-filter based strawman for suppressing duplicates as discussed in §3 configured with the same memory use has a miss rate of 0.2%. Overall, this confirms that SketchLib offers a more practical alternative to the infeasible, inaccurate, and/or expensive strawman solutions from §3.

6.6 Other Benchmarks

Additional Network Functions. After optimized with SketchLib, sketches can even coexist with additional network functions such as L2/L3 forwarding, L4 load balancer, and stateful firewall. Table 12 shows resource utilization for additional network functions.

Code simplification. In addition to the resource efficiency benefits, our optimizations also simplify the sketch implementations by reducing the lines of code, as shown in Table 13.

Compilation time. We also measured compilation time to see whether our modified code will add significant overhead to the compiler. We measure compile time is measured on the server specified in (§6.1). For most cases, there was a negligible (≤ 1 second) increase (not shown).

7 Related Work

Programmable switches. The programmable switch architecture was introduced by Bosshart et al [15]. Subsequent work proposed a programming framework [14], functional hardware [1], and also compilation workflows [34]. Other

Sketch	CS	HLL	UM	RHHH	MRAC	MRB	PCSA
Before	201	290	460	471	261	317	305
After	131	112	127	128	91	94	93

Table 13: Lines of code simplification (UM stands for UnivMon).

vendors have developed programmable pipelined architectures and compilation workflows from P4 or P4-like primitives [4, 5]. While our focus is on Tofino, our approach could be useful for other platforms as well.

Optimizing sketches. HashPipe [46] focused on heavy hitter detection, but is not feasible in the current hardware. Other work has focused on the optimizing sketching algorithms in software switches (e.g., [31, 40, 51]). However, some of their ideas do not translate into a hardware context. For instance, NitroSketch increases the memory footprint to reduce CPU consumption, but the key bottleneck in hardware is different. Similarly, other approaches split a sketch into a fast and slow path on the software switch (e.g., [31]). Unfortunately, this is not relevant in hardware since we need all operations to be in the fast path. Some recent work [51, 52] specifically focus on optimizing UnivMon for embedded platforms and software switches. We translate these insights to a switch hardware realization, and generalize beyond UnivMon.

Control plane reporting. While this work focuses on optimizing data plane components of sketch-based monitoring, there are other challenges in accurately retrieving sketch counters in the control plane. Naïvely retrieving the counters using the existing control plane APIs can result in poor accuracy due to a nonnegligible amount of read and reset delays. We analyze this problem and suggest recommendations in parallel work [44].

Other work in network telemetry. Our focus in this paper is on sketch-based telemetry. There are other efforts for complementary monitoring capabilities (e.g., [29, 30, 48]) and performance-oriented objectives (e.g., [28, 45]).

8 Conclusions

Given increasing traffic rates and rich telemetry required, we see the confluence of two trends: the use of sketching algorithms and programmable switch hardware. Unfortunately, existing sketch implementations are not efficiently realizable, thereby limiting their effectiveness and coexistence with other switch functions. To this end, we systematically analyze the resource bottlenecks, suggest correct-by-construction optimizations, and design a practical library to help developers use these optimizations. Our evaluations show that the SketchLib library is broadly applicable to many sketches and reduces their resource footprint while achieving similar accuracy.

This work focuses on a single sketch-based monitoring task written using SketchLib APIs. We plan to support multiple tasks on a switch and automate the optimizations by integrating our techniques with a compiler as future work.

A   Comparison of RMT resource mapper and Tofino compiler

To validate RMT resource mapper as a proxy for Tofino compiler, we conduct experiments to compare resource allocation results of RMT resource mapper and the Tofino compiler. We pick five different sketches (UnivMon, R-HHH, PCSA, HLL, and MRB). We vary one parameter of sketches while fixing other parameters and analyze the resource allocation results. We focus on five different resource types; pipeline stages, hash calls, SALU, SRAM, and TCAM.

Fig. 18–Fig. 22 illustrate the results. Note that all of the resource usages are normalized. We can see that for hash calls, SALU, SRAM, and TCAM usages are identical between RMT resource mapper and the Tofino compiler. For pipeline stages, results are the same for PCSA, HLL, and MRB. However, RMT resource mapper finds mapping which uses fewer pipeline stages than the Tofino compiler for UnivMon and R-HHH. RMT resource mapper minimizes stages while the Tofino compiler finds more sparse mapping (e.g., mapping a small number of tables per stage). We validate both of the mappings from RMT resource mapper and Tofino compiler are valid. We confirm with the vendor that the Tofino compiler uses complex heuristics and the cost function of power budget and compilation time, which are different from that of RMT resource mapper and can introduce the gap. Our extensions to the RMT resource mapper is available at [6].

Abstract

Modern datacenters support a wide range of protocols and in-network switch enhancements aimed at improving performance. Unfortunately, the resulting protocols often do not coexist gracefully because they inevitably interact via queuing in the network. In this paper we describe EQDS, a new datagram service for datacenters that moves almost all of the queuing out of the core network and into the sending host. This enables it to support multiple (conflicting) higher layer protocols, while only sending packets into the network according to any receiver-driven credit scheme. EQDS can transparently speed up legacy TCP and RDMA stacks, and enables transport protocol evolution, while benefiting from future switch enhancements without needing to modify higher layer stacks. We show through simulation and multiple implementations that EQDS can reduce FCT of legacy TCP by 2x, improve the NVMeOF-RDMA throughput by 30%, and safely run TCP alongside RDMA on the same network.

1 Introduction

Data center networks suffer from a range of unique problems that make it hard to effectively utilize the potential of the underlying high performance redundant multipath network topology. Notable issues include incast traffic patterns, flow collisions and transient congestion due to flow-level load balancing, interference between low-latency request/response traffic and bulk transfers, increasing requirements to offload work from the host CPU to avoid host stack bottlenecks, and the need to support special-purpose high performance protocols such as RDMA in the same network as legacy protocols.

These are all partially solved problems. There is a strong trend towards NIC offload, with datacenters deploying smart NICs and increasing ASIC support for specific transport protocols being offered by NIC vendors. However, moving transport state into NICs makes it harder for dissimilar protocols to coexist, and risks embodying the status quo in hardware.

At the same time, the research community has proposed a rich set of solutions such as phost[14], Homa[31], NDP [18], 1RMA [42] and Aeolus[20] which tackle incast and, to varying degrees, also address issues of load-balancing and low-latency request/response traffic. What these solutions share is a receiver-driven control loop that tightly manages inbound traffic, eliminating large in-network queues. Each of these, by

itself, would be a substantial improvement on the status quo, but datacenters cannot simply migrate to a single new transport protocol. Even if there were buy-in as to which transport protocol to adopt, there are far too many legacy applications and operating systems that would need to be re-written. How then can we take the best ideas from the research community and deploy them in production while supporting a plethora of legacy protocols ranging from vanilla TCP to RDMA?

One strawman solution would be to simply pick a low latency receiver-driven transport protocol and tunnel all datacenter traffic over it. The great advantage of such a control loop is that it performs admission control to the physical network, allowing very small switch buffers to be used while still providing low end-to-end loss. Is it possible to use this to provide a new datagram service that higher layer protocols such as TCP, DCTCP or RDMA run over?

The difficulty is that TCP, DCTCP, RDMA and other protocols each have their own expectations when it comes to sharing the underlying network. In particular, they use interactions between flows mediated via queues in the switches to drive their own control loops. We cannot just eliminate switch queues and expect everything to still work - rather we need to move the queuing from the switches back to the network edge, either in the host or NIC. The low-latency control loop can then clock packets from these edge queues into the network.

We have designed and implemented just such a layer called Edge-Queued Datagram Service (EQDS). Rather than a regular transport protocol, EQDS provides a datagram service to higher layers, implemented via dynamic tunnels. Its receiver-driven control loop is loosely based on NDP and 1RMA[42], but can be extended to utilize other in-network mechanisms where these are available.

Moving the interaction between flows out of the switch queues and back into EQDS edge queues provides many advantages. The receiver directly controls when enqueued packets from different senders enter the network, ensuring isolation even when higher layer protocols run different control loops. For example, TCP and RDMA will not normally coexist gracefully when sending to the same host, but EQDS can mediate, eliminating loss and allowing fair sharing.

Different EQDS queuing disciplines can be also used for different protocols, each providing appropriate feedback to the higher layer control loop; this both improves higher layer protocol performance, and it also allows dissimilar protocols sending from the same host to be protected from each other.

Figure 1: Fragmentation of datacenter networking

Adding new queuing disciplines to support innovative future transport mechanisms is also simplified as they only need to be deployed in the relevant sending hosts, not in switches.

Finally, EQDS uses packet spraying to balance load evenly in the network core, avoiding flow collisions, and increasing throughput. Legacy protocols such as TCP and RDMA do not normally cope well with reordering, so EQDS implements a reorder buffer in the receiver. With a conventional network such a reorder buffer might deliver the highest latency seen across all paths, but with good load balancing and short switch queues we find that EQDS reorder buffer latency is minimal.

In this paper we detail the design and implementation of EQDS and its on-demand zero-RTT tunnel protocol, and evaluate it running both natively in Linux hosts and offloaded to two brands of smart NIC. We show that the EQDS control loop operating on very short timescales does not adversely affect higher layer control loops such as TCP's Cubic or RDMA using DCQCN. Rather, it allows diverse higher-layer control loops to co-exist gracefully, protects latency-sensitive applications from queuing delays caused by bulk transfers, while increasing throughput by eliminating flow collisions.

2 Motivation

IP has been the narrow waist[7] of the Internet stack since from the early days of the Internet, providing basic end-to-end service. In reality, the narrow waist is not just IP: a functioning Internet also assumes some form of TCP-compatible congestion control and sufficient in-network queuing for it to do its job, though this lacks a clear layer in the stack.

This lack of abstraction has particularly hurt datacenter networking. Here, a plethora of work has pushed optimizations across boundaries, including to the host stack, switches or both. As a result of all these enhancements, what has emerged are multiple parallel stacks, each assuming a slightly different "basic" datagram service, that must be isolated from each other in the network to avoid them fighting (see Fig. 1). Further, optimizations for one stack often hurt the performance of others in the same network.

Many have improved on TCP congestion control[1, 28, 44], reducing vanilla TCP's need for large switch buffers. These TCP's are still built upon basic datagram service though, and probe network capacity to sense congestion. In so doing they interact with each other via queues, increasing latency.

Even datagram service itself has been tweaked, with many enhancements aimed at improving service for certain traffic classes, as in Fig. 1. For example, RoCEv2 can use PFC to provide lossless service as assumed by RDMA; this brings its own set of unique feature interaction problems [16, 29].

Protocols like TCP and RDMA also assume largely in-order delivery from the underlying datagram service. In datacenters, in-order delivery is provided by flow-level ECMP, though this wastes capacity in Clos topologies. To better use multipath networks, variants of these protocols have been proposed [38, 26, 29] but rarely deployed. Another source of performance problems as network speeds have increased has been the end-host stack implementation itself. Even TCP resorts to segmentation and checksum offloading, but application writers often use kernel bypass mechanisms such as DPDK or even offload all the work to the NIC using RDMA, and in so doing impose unique dynamic load on the network.

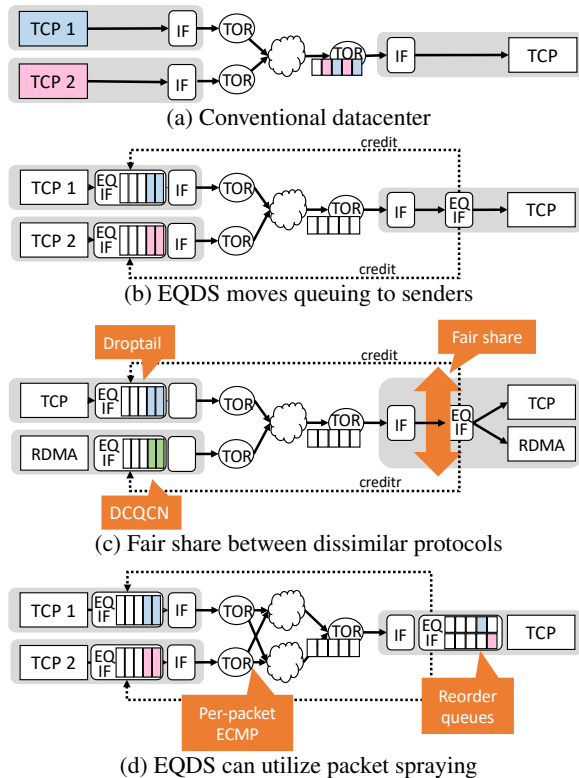
The web of dependencies between higher layer protocols and in-network enhancements makes deploying new protocols increasingly difficult. The root cause of the problem is that basic datagram service forces diverse higher layer protocols to interact via queues in the network. We argue that in-network queuing, beyond the minimum needed to smooth fan-in, is antithetical to building a high performance low-latency general-purpose datacenter network.

We propose a novel Edge-Queued Datagram Service as the new narrow waist for the datacenter networking stack. To transport stacks above, EQDS offers a what looks like a conventional datagram service via virtual interface queues in the host that buffer traffic and provide appropriate congestion feedback signals. EQDS then sends this traffic when possible, utilizing diverse in-network mechanisms to maximize utilization and minimize in-network queuing latency. EQDS shares the network at the hosts, allowing conflicting transports to run side-by-side on the same network.

3 Concept

We introduce the EQDS concept by means of example. Consider Figure 2a: two TCP senders send to a receiver across a conventional network where the bottleneck is at the final hop as is common in datacenters [5]. TCP needs to build a queue to sense congestion and back off, forcing any other flow sharing the queue to behave similarly to share the link reasonably. RDMA or other transports (see Figure 1) that do not will cause problems and need to be isolated from TCP.

In contrast, the EQDS concept is shown in Figure 2b. The underlying latency across modern datacenter networks is so low that protocols like NDP, Homa and Aeolus can use credit mechanisms whereby the receiver clocks packets from the sender as required, ensuring a standing queue never builds in the network. Protocols like TCP still need a queue to drive their control loop, but EQDS moves this queue to the sending hosts, where it is under the receiver's control. If many TCP senders create an incast, the default behavior they observe is almost identical to what would happen if the last hop switch runs fair queuing with a large amount of buffering.

As the queuing has been removed from the network itself, EQDS can run different queuing disciplines in the sending


(a) Conventional datacenter

(b) EQDS moves queuing to senders

(c) Fair share between dissimilar protocols

(d) EQDS can utilize packet spraying

Figure 2: Overall EQDS concept

EQDS Virtual Interface (EQIF), as appropriate to the traffic being carried. Figure 2c shows a legacy TCP sender coexisting with an RDMA sender, with the bottleneck link being shared fairly, or with a proportional share, if that is deemed appropriate by the network or host administration policy.

Finally, Figure 2d shows EQDS using per-packet ECMP (aka packet spraying) in the underlying network to minimize latency and increase network capacity. Few current transport protocols cope well with the level of reordering this usually causes, but as EQDS keeps network queues very small, the reordering is easily managed by a short reorder queue in the receiving EQIF, so it is hidden from the higher level protocol.

In summary, the key EQDS concepts are: (1) move queuing out of the network leaving just the bare minimum required; (2) queue traffic in the sending host; release it when the receiver requests it; (3) run appropriate queue disciplines for different classes of application as they require; and (4) use per-packet ECMP to load-balance evenly so as to minimize latency but, by default, hide it from higher layer protocols. The EQIF virtual interfaces then become the control points for the network, enforcing sharing policies.

4   Design

To implement EQDS, we need four main components:

- One or more EQIFs on the sending host, which implement queuing disciplines to support higher level protocols;

- One EQIF on the receiving host, which implements a short reorder queue for best-effort in-order delivery service to protocols that are intolerant to reordering;

- A mechanism to encapsulate packets reliably across the network from sending EQIF to receiving EQIF;

- An edge-to-edge control loop to clock packets from sending EQIF to receiving EQIF.

With these in place diverse higher-layer protocols are carried over EQDS, which hides lower-layer in-network mechanisms. The edge-to-edge control loop may differ in different datacenter environments or even within one datacenter, depending on switch capabilities. In effect, EQDS has become the new narrow waist of the datacenter protocol stack.

In the virtualized protocol stack, EQDS operates at the same layer as VXLAN, encapsulating higher-layer traffic going to EQDS-capable destinations. To provide datagram service, EQDS needs to provide on-demand tunneling from EQIF to EQIF without prior setup, without spending an RTT performing a handshake to establish control state, and with the expectation that packets sent in the first RTT will be reordered by per-packet ECMP. This demands a novel tunnel protocol (§5). EQDS tunnels are unidirectional; two are setup, one in each direction, if user traffic is bidirectional.

EQIF per-destination tunnel state is established on packet receipt at the sender, and established at the receiver using a zero-RTT protocol. This state can be unilaterally discarded when idle at any time by either side to reduce memory usage and will simply be reestablished as needed.

4.1   EQDS control loop

Critical to EQDS performance and minimizing in-network queuing is the edge-to-edge control loop. EQDS allows different control-loop mechanisms to be used depending on the underlying network capabilities.

For a fully provisioned network our preferred in-network mechanism is packet trimming, which allows EQDS to use an NDP-derived control loop. This allows a burst of packets to be sent in the first RTT before credit-based control from the receiver takes over for subsequent RTTs. The sending EQIF keeps packets until they have been acknowledged by the receiving EQIF, or retransmits them on receipt of a NACK. In this manner, EQDS provides a highly reliable service, but it does not guarantee no packet loss whatsoever. A full reliability guarantee would prevent EQDS managing its own state effectively, risk resource starvation attacks, and would be pointless as full reliability requires end-to-end acknowledgment whereas EQDS may be implemented in the NIC so cannot protect data all the way to the receiving process.

Where packet trimming is unavailable, EQDS uses a 1RMA[42]-derived mechanism where the sending EQIF requests credit from the receiver, or it can use a Homa/Aeolus-derived mechanism where the first RTT of data is sent using
Figure 3: Multiple stacks run on the same substrate.

Figure 4: Tunnel Headers for Data / Control Packets

low-priority service. In an underprovisioned network, core network congestion is also possible, though it should be rare if per-packet ECMP is used. In such cases, in-band network telemetry (INT) might by used to implement an HPCC-style control loop. Our current implementation supports both NDP-style pro-active transmission and request-to-send. We expect future networks to innovate further in this area.

EQIFs. EQDS allows multiple protocol stacks to run on the same network substrate, as shown in Figure 3. The DPDK-based stack on host *A* is sending to its peer at *D* while a virtual machine at *B* also uses TCP to send to the VM at *D*. Without EQDS, the DPDK stack will saturate the link to *D*, starving TCP. This could be prevented using fair queuing in *D*'s ToR switch, but EQDS achieves the same effect without needing to configure switches and with finer grain control.

At *D*, a single *receiving EQIF* receives the flows from *A* and *B*. It maintains state (reorder queues, sequence numbers, etc) for incoming EQDS tunnels, allowing it to effectively manage all incoming traffic. By default, *D*'s receiving EQIF will send equal credits to *A* and *B*, ensuring a fair share and no overload. Proportional sharing or strict priority can also be achieved: the inbound sharing policy can be configured as needed - both by the network administrator and, if the VM and native stacks are run by the same user, by them too.

Three different stacks are in use at *A*: there are RDMA and TCP flows to *C*, a TCP flow to a VM at *B* and the DPDK native flow to *D*. This results in three *sending EQIF* virtual interfaces at *A* for the three different edge queue disciplines. The two TCP flows share the same sending EQIF which runs a TCP-compatible queue discipline. All three EQIFs at *A* cooperate using deficit round robin, so if the total traffic saturates *A*'s outgoing link, they will share it fairly (or unfairly, if that is the configured policy).

To summarize: an EQIF is a virtual interface that implements a specific queue discipline or feedback mechanism to higher-layer protocols. One sending EQIF contains multiple queues, each feeding an EQDS tunnel to a single host. Multiple transport flows from multiple VMs can share one EQIF so long as the protocols used can coexist in the same queue.
5 Tunnel protocol

To carry data from sending EQIF to receiving EQIF we need a new tunnel protocol. The primary requirements are:

- A receiving EQIF should clock packets from its set of sending EQIFs so as not to cause in-network queues to build. At the least, this means it will send credit at a rate that does not exceed the receiver's access link speed.

- A receiving EQIF can choose how to distribute credits to senders, with the default being to implement a fair share.

- The tunnel should expect per-packet ECMP service and be robust to reordering this causes. Where possible, the sending EQIF will determine the path taken by each packet.

- The tunnel should provide best-effort reliable and in-order delivery from the receiving EQIF to higher layer protocols. Losses and reordering should be rare enough to minimally impact the performance of higher layer protocols.

- The tunnel should support unreliable, out-of-order delivery to higher layer protocols that prefer minimal latency.

- The tunnel should come up on demand with no pre-data handshake required, and be discardable at any time. If the endpoints end up out of sync, it should self-synchronize.

- The tunnel should be able to take advantage of a range of underlying network enhancements without higher layer protocols needing to be aware of them.

- Both sending and receiving EQIFs should be able to impose policies for sharing, configured by the network operator and by the users (to the extent user policy does not conflict with operator policy).

- EQIFs must be capable of being implemented in fast NIC hardware with bounded memory resources.

These requirements necessitate an unusual tunnel protocol; it has many aspects of a transport protocol, but is soft-state, being established, dropped and reestablished based on packet arrivals, yet it provides fine-grain closed-loop control.

At a basic design level, EQDS is a tunneling protocol with an NDP-derived control loop, that runs on top of UDP. It can carry multiple types of traffic, including IP and VXLAN. Its control fields (shown in figure 4) were meant to complement VXLAN and there is no overlap in functionality between the two; indeed, EQDS could be implemented as a stateful extension to VXLAN encapsulation if required [1].

Data Clocking. As with NDP, the receiving EQIF sends PULL packets containing credit to the sending EQIF; the

---

[1]For testing, we encapsulated plain IP traffic, rather than VXLAN.

sending EQIF then sends data packets matching that credit from the corresponding tunnel queue in response. The receiving EQIF paces the sending of credit so that after the first RTT the aggregate arrival rate matches the incoming link speed.

To summarize NDP as described in [18]: when a sender starts, one RTT of data is sent without waiting for credit; after that, the sender waits for PULL packets from the receiver. This means that there can be an incast in the first RTT where loss occurs. NDP copes with this using *packet trimming* - the payload is removed from packets that would overflow the queue, and just the header is forwarded to the receiver. This makes the network lossless for metadata, though not for data, and informs the receiver of demand. The receiver can then request retransmission of trimmed data and transmission of new data using PULL packets. In a large incast it may take some time to send a PULL to a sender, so the receiver ACKs or NACKs each data packet so that the sender knows which packet buffers to free and which to add to its retransmit queue.

Where the underlying network supports trimming, an EQDS tunnel uses the NDP mechanism as described above for the first RTT, as it minimizes latency. EQDS supplements this with a request-to-send mechanism, where the sender directly requests credit from the receiver. This is used when trimming is unavailable and for intermittent bursty flows.

Conceptually, each EQDS tunnel maintains a constant bandwidth-delay product (BDP) of credit which is passed between sender and receiver. This credit either starts at the sender (NDP-like) or at the receiver (RTS). Credit flows from sender to receiver with data packets and from receiver to sender with PULL packets. EQDS differs from NDP in how it keeps this window constant in the presence of control packet loss, as NDP failed to do so in corner cases.

EQDS credit is expressed in bytes. To send a packet of size b bytes, the sending EQIF must possess b bytes of credit. PULL packets contain a *pull number* which starts at zero and increments for each PULL sent to a source. When the highest pull number seen by the sending EQIF increases by n, this grants n MTUs of credit.

When a sending EQIF sends data, a *pull target* field in the header indicates to the receiver how much credit is desired beyond the current pull number. This is capped at one bandwidth-delay product (BDP) - typically 10 to 30 packets.

The receiving EQIF maintains an *active sender list* (ASL). An active sender is an incoming EQDS tunnel that has outstanding data to send. Every MTU-time the receiving EQIF will send one MTU of credit to the sender at the head of the ASL. If this causes the pull number to reach that sender's pull target, this credit will satisfy all the known demand from that sender. The sender will then be removed from the ASL and placed in an inactive senders set. If the pull number does not reach the pull target, the credit sent will not yet be sufficient, so the sender is re-inserted at the tail of the ASL. In this way all active senders get a fair share of capacity and credit is not sent to sending EQIFs that have no queued data.

The ASL is similar in concept to the NDP pull queue, but unlike NDP it ensures that a one-BDP credit window invariant always holds. Conceptually, the sum of credit stored at the sender, packets in flight, pulls in flight carrying credit, and credit implicitly stored in the ASL entry at the receiver is a constant so long as sufficient demand remains.

Implementing the ASL as a FIFO ensures incoming traffic is split fairly by default. To implement other sharing policies, a PIFO queue[43] can be used in place of a FIFO, allowing a wide range of policies to be implemented.

To avoid sources going idle and then immediately bursting again, the receiving EQIF tells senders the minimum time its access link will be saturated using the busy time field in control packets (the pull targets inform the receiver of the total queue size at every sender). Even in trimming networks, if a bursty sender restarts within this busy time, it always uses RTS before sending, as bursting would cause unnecessary trims; senders can burst after the busy time elapses.

Tunnel setup and teardown. A sending EQIF creates tunnel state when packets for a new destination arrive. It picks a sequence number with certain constraints (see Appendix A for details) and starts encapsulating packets without waiting for a handshake to complete, setting the SYN flag in all packets until it receives a matching SYN+ACK packet in response. This informs the receiver of the new tunnel and is robust to reordering caused by per-packet ECMP.

Either side can unilaterally drop tunnel state. As an optimization, each will inform the other when it does so, but such a teardown does not need to be signalled reliably, and neither end keeps time-wait state. Later, if new packets arrive at the sending EQIF, a new tunnel will be established. If a receiver tears down a tunnel from a sending EQIF that has queued packets, a new tunnel is immediately set up.

This simplicity allows the simple EQDS state machine in Appendix A, it allows EQDS to be self-synchronizing if the two endpoints end up in different states, and it minimizes state requirements - something that is important for EQDS implementation in hardware. We can get away with such a lightweight protocol because the EQDS service model only guarantees a best-effort attempt to avoid loss, duplication, or reordering. A conventional transport protocol like TCP needs to provide firmer guarantees to the application.

Reorder Queue. Per-packet ECMP greatly improves load balancing, reducing in-network queuing and latency, but may cause reordering. Trimming also causes reordering while awaiting retransmission. To avoid performance problems with higher-layer protocols, EQDS maintains a per-tunnel reorder queue in the receiving EQIF. With minimal in-network queuing, the delay difference between paths is small, so this queue does not grow much and is bounded by a BDP.

Oversubscribed networks. When the network core is oversubscribed and becomes a bottleneck, aggressive receiver-driven transports can result in high trim rates or in high la-
Figure 5: Transmit datapath for sending EQIFs

Figure 6: RDMA EQIF implementation.

tency or loss when RTS is used. In such cases, EQDS will need to be enhanced to take into account other congestion signals such as ECN, latency or even in-band network telemetry[32] *in addition to* receiver pacing. As the receiver-driven transport handles the high-dynamic-range incast case, such congestion management only needs a relatively limited dynamic range and can be implemented by either the receiver reducing its pull rate or by then sender reducing its pull target. Developing such mechanisms is future work.

Incremental deployment. EQDS only encapsulates traffic to configured internal address ranges, so external and legacy traffic will also be present in a datacenter. How will they coexist? EQDS's packet spraying diffuses the effects of a flow across many core links, greatly reducing its impact on any legacy single-path flow. In our testbed when trimming is enabled, we use two priority classes to separate EQDS and non-EQDS traffic and ensure low latency for EQDS via small buffers even in the presence of legacy "elephant" flows.

Strict prioritization is probably undesirable as load levels rise, but weighted fair queuing between EQDS and non-EQDS traffic classes can maintain low latency for EQDS flows in the core, so long as the sprayed load-balanced EQDS aggregate does not exceed its allocated share. On ToR uplinks where EQDS traffic is less diffused, legacy "elephant" flows may impact some EQDS paths more than others. EQDS offers accurate per path latency and loss statistics that can be used to perform load-adaptive routing between paths, avoiding transient bottlenecks. Implementing these is future work.

6 Sending EQIF Specialization

Different types of traffic have different expectations of the underlying datacenter network. While a single EQDS tunnel protocol clocks all traffic from sending EQIF to receiving EQIF, higher-level protocols with differing network expectations are supported by different specialized sending EQIFs.

Fig. 5 shows how sending EQIF behaves as a virtual interface. Whenever a higher-layer protocol sends packets via that interface, EQDS encapsulates and enqueues them, pending sufficient credit being available. The sending EQIF maintains one queue per tunnel, allocated on demand if one does not already exist. When a packet is sent, it is moved from the send to the in-flight queue, but not freed until it is ACKed. If is it
NACKed or a retransmit timer expires, it is moved to the tunnel's retransmit queue. When credit is available, retransmitted packets are sent first, then new ones.

Each sending EQIF provides a specific type of service. We currently support three service classes: TCP-compatible, RDMA, and native. They differ in their queue discipline and in how feedback is presented to end-to-end traffic.

When multiple sending EQIFs are in use at the same host, as in Figure 5, credit avoids overloading the receiver's downlink, but credit from multiple receivers can exceed the uplink speed. When this happens, deficit round robin is used to share the physical interface fairly between the various EQIF queues. Queue priorities can also be configured if desired.

Multiple host stacks or virtual machines sending the same traffic class can share the same EQIF. For example, QUIC and TCP may use the same TCP-compatible EQIF, whereas RDMA would use a different EQIF. None of these legacy stacks need be aware they are running over EQDS.

TCP-compatible EQIF Class. Our TCP EQIF implements a simple drop-tail queue for non-ECN traffic and a RED queue for ECN-capable traffic. The goal of the queue is to absorb traffic when TCP is sending faster than the receiver wants. When the queue fills, a packet will be dropped. The queue needs to be large enough that TCP's congestion control can operate and saturate the receiver's link - typically this will be upwards of 30 packets.

The worst case for TCP is when many flows incast to the same receiver. With a default ten-packet initial window, packets will be queued in the EQIF queue until the receiver sends credit, which may take some time. TCP's 250 ms minimum RTO time helps here - even large incasts can usually complete within 250 ms. If packets are queued longer than this, an RTO may occur, but our experience is that even this has little impact on performance; TCP detects a spurious timeout via the Eiffel algorithm[37, 36], corrects its congestion window, and updates the RTO to prevent further timeouts.

We find that vanilla TCP running over EQDS almost always outperforms TCP running natively, even when not competing with incompatible flows. Much of this win comes from EQDS's use of per-packet ECMP.

RDMA EQIF Class. RDMA requires a separate EQIF to avoid fighting with other traffic, to avoid loss seriously impacting RDMA performance, and to provide appropriate flow control feedback to the RDMA implementation.

RDMA is typically implemented in the NIC. Ideally an RDMA EQIF implementation would be coupled with the hardware transport implementation to directly flow-control RDMA traffic. We currently deploy our prototype RDMA EQIF in a smart NIC, as shown in Fig. 6. We use port representors [8] to interpose on RDMA-enabled devices the SmartNIC exposes to the host and its virtual machines.

Our EQIF does not modify the NIC's RDMA implementation, but it does need to tell the sender to slow down when the TX queue to a destination grows. Depending on the SmartNIC model, we use different techniques to control the sending rate of the RDMA engine. For the Stingray, we issue PFC PAUSE packets to slow down the sender; this works well, but it has the side effect of slowing all traffic coming out of the RDMA engine, not just the one to the backlogged destination. The BlueField 2 supports DCQCN, so our implementation uses this to control RDMA. We could use ECN to signal DCQCN flows to slow down, but we prefer to send congestion notification packets (CNPs) directly from the sending EQIF to the RDMA sender. This reduces the length of the DCQCN control loop and allows one-time tuning of the DCQCN parameters to this constant delay. Unfortunately, RDMA RC packets lack the source QP number in their headers, which is needed for sending back a response, so we develop a connection tracking module [10] for RDMA CM, enabling CNP generation.

Our current smart NIC implementation moves packets from the host to the ARM cores and then to the wire; with bidirectional traffic the SmartNIC's interconnect can become a bottleneck. It should be possible to only move the packet headers to the ARM cores, but our implementation does not support this yet. To avoid our results being affected we configure our RDMA testbed to a lower rate (10 Gbps). A NIC designed for EQDS would not add this additional latency. Despite this, our implementation increases RDMA performance in many cases while allowing coexistence with other protocols.

The Native EQIF is the preferred option for performance-oriented, EQDS-aware transports. It uses a shared memory area to store packets with lockless descriptor rings used to move packets to and from the EQIF via a zero-copy API. This EQIF offers additional low level information to host transports including the size of the TX buffer to the destination, the size of the destination's pull-queue, per-packet and per-path network RTTs and delivery notifications.

Latency information provided by the Native EQIF is similar to that provided by 1RMA, so for cases where core congestion is common, delay-based congestion controllers such as Swift [24] or Timely [28] can be implemented on top.

We have implemented *eqdsperf*, a performance testing tool over the Native EQIF, as well as a lightweight UDP stack that is optimized to run over EQDS. Applications using the UDP socket API can simply be linked to our stack, either statically at compile time, or dynamically using LD _PRELOAD.

7   Implementation

We implemented two versions of EQDS, one using DPDK and one as a Linux kernel module. The goal is to add minimal overhead, but inevitably there are tradeoffs to be made.

Our DPDK implementation was built with performance in mind and uses two CPU cores, regardless of load. These can be host CPU cores, but it is preferable to use the ARM cores on a smart NIC. The main thread takes turns reading packet batches from the host-facing and network-facing NICs. Once read, packets are processed to completion. At the sender, this includes NACKs and PULLs triggering the (re)transmission of queued packets, and at the receiver trimmed packets elicit NACKs while packets that fill a hole at the head of the reorder queue trigger the release of waiting packets. The main thread also checks for timer expiration, largely eliminating the need for synchronization. A second thread is used to pace PULLs and to send deferred ACKs, providing accurate PULL pacing at the expense of burning a second core. When the NIC supports fine-grained pacing (e.g. Intel Columbiaville), EQDS can offload pull-pacing to the NIC, reducing CPU usage.

Our kernel implementation is aimed at being cheap and easy to deploy. As is usual on Linux, outgoing packets are processed in the context of the sending process. They are captured by a hook after routing has taken place. If there is enough credit, processing continues until they are handed to the NIC's driver. Inbound, EQDS acts like a UDP service; all incoming packets, both data and control, are processed in a soft IRQ and fed to a kernel UDP socket. Data packets that can be forwarded straight away are re-injected into the IP stack after decapsulation. If control or data packets have to be sent back, a Layer 3 socket is used.

High Resolution Timers are used for PULL pacing with their handlers executed in a soft IRQ. The downside of using kernel timers is that their timing is at the mercy of the Linux scheduler. This adds jitter to the PULL pacing. To mitigate such jitter, senders must use higher window values than usual.

Offloads are key to achieving high TCP performance with Linux, so our implementation leverages both TSO and GRO. With TSO, TCP will send large segments, EQDS will encapsulate them, then an EQDS-unaware NIC will split the encapsulated packet, copying the extra headers verbatim in front of the inner TCP/IP headers. The problem is that all the split packets will have the same EQDS sequence number. Fortunately, due to a peculiarity in how TSO is performed, there is a workaround. A NIC increments the IP ID of every segment following the first. We send all EQDS packets with an IP ID of zero, and leave gaps in the EQDS sequence space. The receiver then adds the received IP ID to the received sequence number to obtain the full sequence number. Future EQDS-aware NICs would remove the need for this workaround. Inevitably, using TSO causes a burst of unpaced packets to be sent which, as with timer jitter, requires a small increase in the window used by EQDS.
Figure 7: Permutation throughput in the T2 testbed (BlueField-2 hosts).

8 Evaluation

Datacenter networks have been shown to suffer from a number of pathologies including reduced throughput due to flow collisions, high loss or delay due to incast, inflated latency for RPC-style traffic and a dependency on compatible congestion control mechanisms for network sharing. EQDS's main goal is to enable the deployment of known solutions to all these problems in actual networks, and to make the resulting performance available to unmodified host stacks.

The first part of our evaluation examines whether EQDS helps mitigate these known pathologies and can boost performance for regular datacenter applications. To ensure the results are not specific to one host stack or deployment model and do not depend on network support, we experiment with unmodified TCP/IP (Linux) and RDMA NIC stacks (Blue-Field 2, CX4), run EQDS both on the host and on two smart NICs, and use both legacy and trimming-enabled networks.

We find that EQDS helps boost throughput of unmodified TCP/IP and RDMA stacks by up to 30-40%, mitigating the effects of collisions in a permutation traffic matrix (§8.1) and for NVMe over Fabric traffic. It achieves near-perfect incast behaviour with very small in-network queues both with trimming (our testbed and simulation) and RTS (on Amazon EC2), halving the latency and doubling the throughput of a micro-service based social network application benchmark on busy networks, as well as speeding up memcached by 10-30x (§8.2). Finally, we show that EQDS helps conflicting upper-layer congestion controllers nicely share the underlying network without any in-network support (§8.3).

In the second part we seek to understand whether EQDS introduces problems of its own. The biggest concerns are host overheads such as EQDS software's memory and CPU costs, its ability to handle high link speeds and dependence on specific hardware for performance.

In our evaluation we used two small-scale testbeds: T1 is a testbed we used for TCP/IP tests (10 servers) and T2 for mixed RDMA and TCP/IP tests (6 servers). Both testbeds used leaf-spine topologies and support trimming, but can also be configured with drop-tail/ECN; a detailed testbed description is provided in Appendix B. To test behaviour at scale and behaviour over legacy networks we use a large scale deployment in Amazon EC2 as well as simulation.

8.1 Improving throughput

TCP and RDMA require in-order packet delivery to function well, so datacenters switches hash the packet 5-tuple to select one of many equal-length paths to the destination. However, when the number of flows is small and the flows are high bandwidth, such placement can randomly place multiple flows on the same link causing congestion. Prior work has shown that flow collisions degrade performance in folded Clos topologies [11, 38] by up to 60% in the worst-case where a permutation traffic matrix is used, where each host sends to and receives from one other host. EQDS's per packet multipath should avoid such performance loss, at the cost of performing reordering in the receiving EQIF. We have run permutation experiments for RDMA in testbed T2 and for TCP in testbeds T1 and T2 as well as in simulation at larger scale.

Figure 7 shows that EQDS successfully spreads single flow TCP and RDMA traffic over all the available paths without causing reordering problems. TCP and RDMA flows running over EQDS achieve 22Gbps on average (maximum 24Gbps) in a permutation traffic matrix, compared to an average of 12-14Gbps without EQDS.

Our simulation results in Figure 8 explore behaviour at larger scale (FatTree with k=16, 1024 servers, 10Gbps NICs). Flow collisions hurt TCP badly, yielding only 40% of the network capacity. Multipath TCP[38], a variant of TCP that spreads traffic over multiple subflows (8 in our experiment) fares better with mean utilization close to 90%. NDP's packet spraying enables it to achieve near-optimal throughput. Finally, TCP over EQDS benefits from packet spraying but avoids the costs of reordering which is handled by EQDS, achieving similar performance to NDP.

Permutation traffic matrices highlight worst-case behaviour, with infinite flows and the smallest number of flows possible. Do collisions actually matter for other traffic matrices, for shorter flows, and for real applications? We examine this next.

1MB flows, random traffic matrix. On our testbed we run a workload where each server downloads a 1MB object from another randomly chosen server in a closed-loop, mimicking a storage workload over TCP. We measure flow completion times and plot them in Figure 9. EQDS lowers median and 95th percentile completion times by 2.4x and 2x respectively.

We also ran the same experiment with EQDS using request-

Figure 10: Ping latency: target is idle or busy with 9 incoming TCPs (T1 testbed).

Figure 11: DeathStarBench in the T1 testbed: request latency

Figure 12: DeathStarBench in the T1 testbed: throughput

to-send and without trimming support in the switches. The flow completion times (FCT) for this setup are, as expected, slightly larger than the NDP-based implementation due to the additional RTT needed at the beginning of transfers. Still, EQDS/RTS halves the completion time of TCP compared to baseline, both in the median and at 95%. At 99% all variants have similar FCTs, and beyond that EQDS can take longer due to missing optimizations in the code for short flows.

NVMeOF. We run a disaggregated storage service using a Storage Performance Development Kit (SPDK) NVMeOF-RDMA target with a null block device (i.e. no storage access) to stress the network subsystem. The NVMeOF-RDMA protocol is target-driven, with the server reading or writing to memory buffers in the client after coordinating the access via rendezvous. This involves both latency-sensitive operations for control and throughput-hungry operations for data.

We run the NVMeOF targets and clients on separate ToRs. Each client accesses the targets round-robin, using the SPDK `perf` utility to generate the workload. Figure 13 shows the throughput of random writes and reads of 64 KB blocks while varying the queue depth of the NVMeOF target. EQDS with its multipath support increases both peak read and write throughput and reduces standard deviation. Note that EQDS requires deeper NVMeOF queues to achieve higher throughput due to the added latency of our BlueField setup (§8.5).

8.2 Improving application latency

In deployed networks, there is a strict tradeoff between supporting many-to-one incast traffic gracefully, typically by provisioning large shared buffers in the network, and the latency of request-response applications such as micro-services or in-memory key-value storage (e.g. memcached). EQDS solves this trade-off by moving the buffering to the sending hosts, promising to achieve both low latency and good incast behaviour simultaneously.

Many to one traffic. To understand the baseline behaviour, we run large many to one workloads (850 iperf senders to the same receiver) in both simulation and on Amazon EC2 VMs.

We use htsim simulation to understand the behaviour of TCP NewReno when the destination link runs at 10Gbps, and we vary the size of bottleneck switch buffer. Figure 14 is
Figure 13: NVMeOF in the T2 testbed (BlueField-2).

a CDF of the flows' mean throughput. When the buffer is small (approx. 1 packet per flow), there is a large variance of throughput, with many flows starved. As we increase the buffer to around 100 packets for each flow, TCP can share capacity much more evenly, and there is no starvation. We also show the result when the switches implement fair-queuing, which further reduces variance and reduces buffer needs.

We run the same workload over EQDS, with the EQIF per-destination buffer set to 100 packets and a 15 packet buffer at the bottleneck. EQDS perfectly shares the bottleneck capacity, emulating a fair queue at the bottleneck link.

While our simulations show that TCP many-to-one requires significant buffering to work well without EQDS, what is the actual behaviour in production datacenters? We rented VMs on Amazon EC2 (m5.8xlarge for the receiver, and m5.xlarge for all others, 10Gbps link speeds) and deployed the Linux kernel version of EQDS, configured to run in RTS mode, as EC2 does not currently implement trimming.

We ran the same workload, with 850 hosts running iperf to one receiver and plot the results in Figure 15. Note the linear x axis for this plot: many to one traffic in EC2 works fairly well, similar to the simulated fair-queuing results. TCP running over EQDS in EC2 achieves almost perfect sharing and 4% better throughput than the baseline, matching our simulations.

To achieve such good sharing, it appears that EC2 uses large buffers. We measure these buffers by pinging the same destination from an idle VM before and during the incast. Figure 16 is a CDF of ping latency. EC2 ping latency increases 163x from $55\mu s$ to 9ms during the 10Gbps incast, indicating that a buffer of around 11MB exists in this network. In contrast, EQDS achieves similar many-to-one throughput with only a $21\mu s$ increase in ping latency.

Is this behaviour specific to EC2 or the RTS backend? We

Figure 14: Simulation: 850 to 1 traffic, varying size of bottleneck buffer.

Figure 15: Amazon EC2: 850 to 1 traffic, kernel EQDS, RTS mode

Figure 16: Ping latency (EC2): target is idle or busy with 850 incoming TCPs.

ran a similar experiment in our testbed using trimming instead of RTS. Figure 10 shows the results. When the destination is busy, EQDS with trimming results in a 36μs increase in ping RTT, similar to RTS on EC2. Without EQDS, the increase is around 500μs because our switch buffers for TCP are 1MB (less than EC2) and the link speed is 25Gbps. In summary, EC2 appears to be using large buffers to cope with incast. How does this affect latency sensitive traffic?

Memcached. We installed `memcached` on our EC2 destination VM and used `memcslap`, a benchmarking client, to measure server performance by issuing 1000 GET/PUT operations in a closed-loop manner. The mean request latency for an idle memcached server in EC2 is 700us. When running over EQDS, the same request takes around 900us due to the additional kernel processing EQDS does and the use of RTS.

When the destination is busy with 100 iperf clients sending to it, the mean request latency over EQDS increases 3x to 3ms, mostly due to sharing bandwidth with iperf, compared to a 140x increase to 100ms without EQDS due to large buffers. With 850 iperf clients sending, memcached over EQDS has a mean request latency of 23ms due to sharing bandwidth with 8.5 times more flows, compared to 400ms over native EC2. Overall, EQDS reduces memcached request latency for a busy EC2 server by 20 to 30x compared to the baseline.

Micro-service apps. We ran the latency-sensitive social network application of DeathStarBench [13] over kernel EQDS. We distributed the micro-service nodes to ensure that most requests are not local and must use the network, and used `wrk` to generate requests in a closed-loop manner.

We tested two scenarios: one where the network was idle, and one where high-throughput traffic going to the same hosts saturated the links filling the switch buffers. We note that the social network application does not generate much traffic – 100Mbps peak – but is latency sensitive so we expect to see an impact of longer network latencies in our "busy" scenario.

Figures 11 and 12 show the results. On an idle network social network requests take ~2ms to complete, with little difference between the baseline and EQDS. Our deployment can sustain a request load of about 500 requests per second after which DSB saturates the CPU. When the network is busy, however, EQDS reduces request latency by 50% and can sustain double the baseline request load.

8.3 Sharing the network

EQDS allows fine-grained host sharing policies without in-network support; we examine some interesting scenarios.

Non-responsive traffic competing with TCP. Consider the scenario in Figure 17 where a receiver in our testbed receives data from 4 TCP senders and then a UDP sender starts sending at line-rate (emulated with iperf3). As the UDP flow does not respond to congestion, the testbed network run in legacy mode allows the UDP flow to use nearly 25Gbps of bandwidth, starving the TCP flows. With EQDS (in trimming mode in this experiment), the UDP sender is throttled at the sending EQIF which enforces perfect ingress sharing, without any need for fair-queuing in the network.

Congestion controllers being nice. In fact, EQDS can enable **any** combination of existing congestion controllers to co-exist fairly without any in-network support. In figure 18 we show the sharing results when two senders send to the same receiver, with one sender using Cubic[17] and the other using the congestion control algorithms shown on the *x* axis label. We used all the congestion control implementations available in the Linux kernel, as well as the Mellanox DCQCN implementation. EQDS is able to fairly share the receiver's link without in-network support for almost all congestion controllers, in contrast to the status quo where latency-based schemes such as BBR[4] are starved by loss-based ones (e.g. Cubic). One exception are the Vegas[2] controllers that cannot utilize the 25Gbps link over EQDS when running alone, and that receive a smaller share when competing against Cubic. This appears to be due to Vegas measuring a small base RTT and stopping the window increase before it reaches a BDP.

The amount of buffering in the EQDS TX queue depends, as expected, on the congestion control algorithm. BBR is best, with an average latency of 243μs when sending at line rate, compared to DCTCP (K=16) at 435μs and Cubic at 1315μs.

RDMA versus TCP. To see how EQDS aids effective co-existence between different host stacks, we run a single TCP and *n* RDMA flows to the same destination in T2 (BlueField NICs). Figure 19 shows the bandwidth distribution among competing flows as the number of RDMA flows varies from zero to four. Without EQDS, TCP fills the switch buffers while DCQCN causes RDMA to back off, with some RDMA
Figure 17: Bandwidth sharing (5 to 1): one non-responsive UDP sender (testbed T1)

Figure 18: Capacity sharing between TCP variants, with and without EQDS (testbed T1)

Figure 19: RDMA and TCP network sharing (testbed T2)

flows being starved. With EQDS, data is buffered at the sending hosts and the bandwidth allocation is determined by the receiver, protecting RDMA and sharing the bandwidth fairly.

NVMeOF in parallel with a TCP shuffle. To understand sharing beyond a single bottleneck link, and to also test the CX4 RDMA stack over EQDS, we run the NVMeOF RDMA benchmark (§8.1) in parallel with TCP traffic emulating a MapReduce shuffle operation on the T2 testbed (CX4 hosts). Specifically, three nodes on one ToR run both iperf senders and NVMeOF targets. These three send to three nodes on another ToR running both iperf receivers and NVMeOF clients that perform random reads.

We observe that with EQDS the TCP shuffle alone is about 30% faster than without EQDS (26.1 Gbps vs 19.6 Gbps), in line with the previous experiments. When both TCP and RDMA run concurrently without EQDS, the shuffle throughput drops to 17.6 Gbps and NVMeOF drops to 2.56 Gbps – far from the optimal fair share. Under EQDS, shuffle and NVMeOF achieve 15.8 Gbps and 10 Gbps respectively, which is both a fairer allocation and higher overall throughput.

8.4 EQDS in legacy networks

To investigate EQDS with an oversubscribed core, we interconnect two ToRs in our T1 testbed with two 25Gbps spine links. Fair queuing is enabled. One ToR hosts three servers (2 at 100Gbps, 1 at 10Gbps); the other ToR hosts eight clients (mix of 10 and 25Gbps links). Each client connects to one server and continuously requests a 1MB object in a closed-loop, creating a new TCP connection each time. Clients are equally balanced across servers.

We increase the number of active clients from 1 (core utilization ≈50%) up to 8 (400% core over-subscription). We plot the median and 99% FCTs for baseline TCP, TCP-over-EQDS with trimming and TCP-over-EQDS using RTS. When the core is lightly loaded, EQDS's packet-level load balancing gives slightly smaller median (Figure 20) and 2x to 5x smaller 99th percentile FCT (Figure 21). As we add more clients and the core becomes overloaded, EQDS ends up behaving similarly to the native baseline, while RTS is slightly slower than baseline as it requires a large amount of buffering. For EQDS with trimming, as the core gets busier the trim rate increases and each packet can be re-sent multiple times. While this does
not affect FCT, it is undesirable; it would be better to reduce the pull rate when core congestion is detected.

Legacy "elephant" traffic. To understand how legacy traffic coexists with EQDS, we use the same configuration but with two clients downloading 1MB objects from two servers, and create a long-lasting iperf3 flow to another client. We vary the throughput for this legacy flow from 0 to 25Gbps and measure the FCTs of the other flows. Figure 22 shows how flow collisions on the spine between native 1MB flows and the elephant flow affects FCT: the median grows by 2.5x when the elephant flow fully occupies the spine link. With EQDS, packet spraying helps mitigate the effects of the elephant flow, and the increase in FCT is modest. A future implementation of load-aware routing should improve things further.

8.5 Host processing evaluation for EQDS

Our experiments so far have looked at how EQDS can help existing stacks, and used 25Gbps (our testbeds) and 10Gbps link speeds (EC2, simulation). We now examine the performance and overheads of our two EQDS implementations and evaluate how they perform at higher speeds. We tested using several configurations:

Setup 1. DPDK on the host, both with native transports and underneath the VM stack, where EQDS takes the role of the software switch used in virtualization.

Setup 2. DPDK on an SoC-based SmartNIC (Broadcom Stingray PS225 or Mellanox BlueField 2) with support for legacy TCP and RDMA traffic.

Setup 3. DPDK on the host, processing RDMA traffic to and from a Mellanox CX4 NIC.

Setup 4. Our Linux Kernel 5.4 implementation, with EQDS kernel module running underneath the TCP/IP stack.

The DPDK implementation is the most versatile and performs best, though this depends on the higher level stack and the setup used (Figure 23). The best performance is given by `eqdsperf` in setup 1 using the zero-copy native EQDS transport. Between two 2.5GHz Xeon Silver 4215 machines with Intel Columbiaville NICs, eqdsperf achieves 40Gbps with 1.5KB packets and 100Gbps with 4KB packets. The bottleneck is the sender; with two senders to the same receiver, the link saturates with 3KB packets.
Figure 20: Median FCT for 1MB flows (oversubscribed core).

Figure 23: EQDS DPDK performance
Figure 24: `eqdsperf` throughput (setup 1)

Stack	MTU	TSO off GRO off	TSO on GRO on
Linux	*1.5KB*	17Gbps	40Gbps
EQDS	*1.5KB*	5Gbps	27Gbps
Linux	*9KB*	40Gbps	60Gbps
EQDS	*9KB*	28Gbps	55Gbps

Figure 25: EQDS Kernel performance (setup 4)

In Setup 1, when we run EQDS underneath Linux VMs in KVM using vhost-user networking, it achieves 27Gbps with 1.5KB packets compared to 40Gbps for the baseline (testpmd). The cost here for both testpmd and EQDS comes from the packet copy from the guest to the host.

In Setup 2 we run EQDS on both the Broadcom PS225 SmartNIC and Mellanox's BlueField 2 NIC. Our EQIF uses one NIC core for each of the two links and one for credit pacing. On the Stingray, EQDS saturates the link with a single core when the MTU is 1.5KB or larger. On the PS225 the results are similar with EQDS reaching 50Gbps with an 8KB MTU. We note that SmartNIC ARM cores are weaker than x86 cores and memory bandwidth seems limited; reaching 100Gbps may require more offloading.

In Setup 3 we divert RDMA traffic from a Mellanox ConnectX-4 Lx NIC via a host core. This is not ideal as it requires an extra round trip across the PCIe bus, but demonstrates RDMA-over-EQDS even without a smart NIC. Since the CX4 PCIe bandwidth is 56Gbps, we limit the link bandwidth to 10Gbps to avoid a PCIe bottleneck. With EQDS, the bandwidth of a single RDMA flow between two RDMA nodes remains the same as with baseline RDMA (Table 23), but the additional PCIe round-trip increases median latency by 9 μs on an unloaded system and by 14 μs under load.

In Setup 4 we run EQDS in a kernel module. Figure 25 shows TCP performance with and without EQDS, and explores the effect of TCP offloads. Our kernel implementation can reach 55Gbps (one core) with jumbograms, or 27Gbps with a 1.5KB MTU. TCP's dependence on offload support is clear. EQDS increases CPU utilization at the sender by 2% and at the receiver by 5% when running an iperf at 55Gbps.

Tunnel setup overhead. When EQDS tunnels are already set up, EQDS only adds a few *μs* of latency, as shown in Fig. 23. When a new host is contacted, however, a tunnel is setup dynamically using a zero-RTT approach. We measure this by tearing down tunnels, then sending a series of pings; the difference between the first ping time and subsequent ones is around 20μs. This setup latency is due to memory initialization costs for the tunnel data structures.

EQDS memory consumption. How does EQDS memory consumption scale with the size of the datacenter? There are three categories of memory to consider.

A Sending EQIF buffers packets awaiting transmission. For TCP, we use 100 packets per destination by default, but we find that if needed this can be reduced as low as four packets per destination when sending to many receivers. For RDMA, the upper marking threshold is set to 375 packets.

The receiving EQIF has a reorder buffer per sender. In the worst case with faulty links, the buffer can reach the EQDS window which is between 50 packets (DPDK) and 150 packets (kernel). In practice this is limited to less than 10 packets.

In-flight packets are buffered at the sender pending retransmission, but the pending buffer size is limited by the BDP. We verify this by starting iperfs to an increasingly larger number of receivers. The total number of in-flight packets across all tunnels saturates at around 400 packets (NIC ring size plus one BDP) regardless of the number of receivers.

With 1.5GB of DRAM, EQDS can buffer packets for 10,000 active destination; this fits in the RAM of the Smart-NICs we used (8-16GB) as well as the hosts. In practice both the number of active destinations and actual buffer utilization are smaller; on EC2 the receiver's memory usage for EQDS did not exceed 100MB with 850 senders.

9 Related work

Tunneling is widely used in datacenters for security isolation of traffic (e.g. VXLAN and GRE). These protocols, however, do not offer any performance isolation between tenants. Rate limiting is typically used in public clouds, but this offers limited isolation, especially for incast workloads.

Numerous research works examined the performance sharing problem [40, 34, 35]. Seawall [40] and ElasticSwitch [35] use rate-limiting between each pair of hosts in a datacenter to manage sharing, and use centrally computed weights to achieve fair sharing among different tenants. FairCloud [34] discusses fundamental tradeoffs in sharing cloud networks. This line of works relies on rate limiting and needs large in-network queues to cope with incast; it also doesn't improve utilization of multipath networks.

Virtualized congestion control works such as VCC [6] and AC/DC [19] propose ways of deploying new TCP congestion variants without VM changes. Both keep per-flow congestion state in the hypervisor, applying rate-limiting techniques (such as receive window reduction) to force the VM stack to reduce its rate; both show how DCTCP can be deployed in this way. OnRamp [3] is a recent proposal that aims to improve the fast start phase of transport protocols by tracking fine-grained RTT measurements per flow, in the hypervisor, and then stopping packets from entering the network when latency increases above a certain threshold. This line of work does not allow multipath transmission of TCP packets or other network-specific enhancements, and still requires large in-network buffers to cope with incast.

EQDS takes the next logical step over this line of prior work: it completely decouples host stacks from the network via edge queues, thus supporting multiple higher layer transports (e.g. TCP, RDMA or native). EQDS does not do rate limiting (because it can build large queues), but uses a receiver-driven control loop instead, ensuring that network queue depths are kept as low as possible. Any sharing outcome for clouds (e.g., [34]) can be configured using the primitives EQDS provides to higher layers. The key benefit of EQDS is decoupling the higher layer transports from lower layer implementations; this enables regular TCP run over packet-sprayed networks, among others.

Fastpass [33], pHost [14], Aeolus [20], NDP [18], Homa [31], qJump [15] are techniques that show how one can operate a network at high load and small queues. In-band network telemetry [32] provides accurate congestion information to endpoints that can be used in over-subscribed topologies (e.g. HPCC [25]). In contrast to all these transport or congestion control protocols, EQDS is a congestion tunneling layer that is meant to allow other transports to operate on top; it can use the mechanisms proposed by any of these or other, yet-to-be-invented, mechanisms to drive packet pacing and ensure that the network core is used efficiently, but it also allows to deploy them transparently to user applications. Our implementation implements both NDP [18] and a request-to-send

variant that does not require trimming.

New transport stacks like PonyExpress [27] or eRPC [23] show the benefits of kernel bypass to support novel APIs, but they face an uphill battle in deployment. EQDS allows such transports to be deployed without changes to the network.

10 Conclusions and next steps

EQDS is a new network layer that provides strong performance isolation among co-existing transports by pulling the shared queues out of the data center network core and moving them to the edge. More importantly, it introduces a new datagram service abstraction which fully decouples the transport services above it from the network implementation underneath, thus enabling independent evolution of these layers while ensuring future compatibility among them.

EQDS is designed for gradual adoption. From the application perspective, RDMA and TCP EQIFs allow seamless deployment of EQDS without any application modifications. In the longer term we envision the emergence of application protocols implemented atop and optimized for EQDS-native APIs, thereby taking full advantage of the improved visibility into the network performance that they offer.

From the network infrastructure perspective, one can use our software-only implementations in Linux kernel, Smart-NIC or/and host that allow the benefits of EQDS isolation to be reaped at low performance cost, and can also run without switch support for packet trimming.

The NIC implementation is ideal from a deployment point of view, as it is cleanly separated from the host software, which can use offloading support as before. Our smart NIC setup, however, adds a little unnecessary latency (12-16us) and is limited to 25Gbps per core at 1.5KB MTU. These limitations should be fixable with NIC ASIC support for EQDS.

There are many examples of existing ASIC and FPGA implementations of connected transport protocols, ranging from RDMA [9, 21, 22, 41], to TCP offload engines [30, 12, 39]. An EQDS NIC would build upon these works, and its hardware version might actually be simpler: keeping state for each connected endpoint rather than per-flow means more connections could be stored in on-chip memory, and its relaxed ordering and reliability guarantees allow implementing a simpler state machine. By offloading control packet processing, we expect to shorten the EQDS control loop delay significantly, and reducing its jitter, thus minimizing switch buffer usage. Furthermore, offloading connection setup and teardown logic would allow low latency small flows to get close to native performance.

Appendix A. Protocol state machines

The state machines for our protocol implementation are shown in Figures 26 (the sender) and 27 (for the receiver).

The aim is for the two endpoints to self-synchronize. The sender sets the SYN flag on all data packets sent until it receives a SYN-ACK (or SYN-NACK or SYN-SACK) packet from the receiver. As a window of SYN packets can arrive out-of-order, the lowest ten bits of the sequence number are always zero in the first SYN packet and the upper sequence number bits in SYN packets indicate an epoch number.

The receiver state machine is very simple, with just two states, `closed` and `established`. As SYNs from the initial window can arrive out of order, an arriving SYN causes the receiver to move to established state and set the initial sequence number to be that from the SYN with the lowest ten bits cleared. Any subsequent SYNs with the same epoch number are treated as normal data packets except the SYN flag is set in their ACKs.

When data arrives at the sender it chooses a random epoch number, starts sending data with SYN set, and moves to SYN-SENT state. It then moves to *established* state on receiving a SYN-ACK with the correct epoch number from the receiver.

The epoch number is needed because either end can drop state at any point. If a sender drops state very early in a connection, then immediately tries to re-establish a tunnel, old SYN packets may still be in flight. The epoch number allows the sender and receiver to agree which is the new connection.

If the sender retains the old epoch number, it simply chooses a greater epoch for the new connection. The receiver then accepts the new SYN as re-establishing the connection seamlessly. However, if the sender has no state, it chooses a random epoch number. If this random epoch number is greater it will be accepted, but if it is lesser, the receiver concludes it is old and replies with a SYN-ACK advertising its current epoch. If the sender receives such a mismatched greater epoch in a SYN-ACK, it concludes the setup has failed, chooses a new epoch greater than that advertised by the receiver, and resends its initial window of SYNs. This new attempt will then always succeed.

It is possible that SYN-ACKs from the previous connection are still in flight when the new connection is attempted. If these have a lower epoch (the common case) they are ignored; if they have a greater epoch they trigger the re-sync process as described above.

If a receiver has outstanding data in its reorder queue when a connected reestablishes, it releases this data to the host out-of-order as it can no longer guarantee the sequence space holes will be filled. This is expected to be very rare in practice as endpoints will not normally drop state with unacked data in transit.

The sender responds to any indication of an unhealthy tunnel by closing it and re-establishing a new tunnel, possibly after a timeout. A large number of retransmit timeouts implies that there is likely a network connectivity issue affecting the tunnel. Similarly, receipt of a RST indicates the receiver is in the `closed` state, and prompts re-establishment of the tunnel if there are packets in the EQIF TX queue.

The key benefit of this self-synchronizing design is that either endpoint can drop state without reliably informing its peer. This gives EQDS implementations a lot of freedom in managing per-tunnel memory, allowing lightly used tunnels to be dropped in memory pressure scenarios. While these ability is not used in our software implementations, we expect that future ASIC implementations of EQDS in NICs will make full use of these features.

Appendix B. Details on the experiment setup.

Our T1 (TCP/IP) testbed has 10 endpoints:

- 8 Linux kernel endpoints emulated on four servers with Intel Xeon Silver 4215 CPUs @ 2.50GHz (8 cores, 16 hyperthreads), 128GB of RAM and a dual-port 100Gbps Intel Columbiaville NIC each (running in Setup 1, with EQDS on the host cores either as part of the kernel or as a DPDK process).

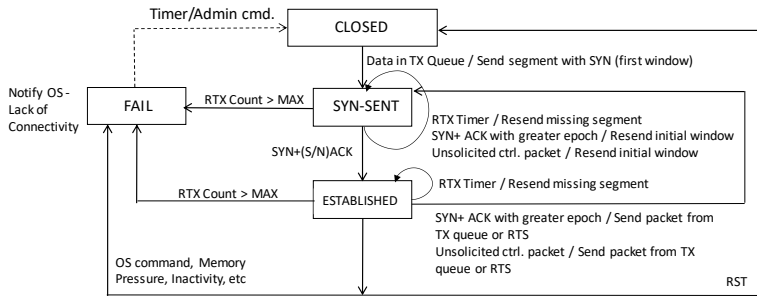
- 4 Broadcom endpoints emulated by two servers with Intel Xeo E5-2650L v2 CPUs @ 1.70GHz, 32GB of RAM (10 cores, 20 hyperthreads), each with a dual-port 25Gbps


Figure 26: EQDS sender state machine

Figure 27: EQDS receiver state machine

Broadcom Stingray NIC (EQDS is running on the Arm cores of the Stingray, in Setup 2).

Each endpoint is connected via a 25Gbps link to a 64-port Tofino 1 switch; we downgraded the Columbiaville NICs to 25Gbps to match the speed of the Stingray NICs. We implemented packet trimming in the switch via a combination of ingress meters and cloning sessions. We used the four pipelines in this switch to emulate four ToR switches; these are connected via DAC cables to two spine switches emulated by another 32-port Tofino (one pipeline per emulated switch). Switch buffers are set to 15 packets (125KB) for EQDS and 200 packets (2MB) for TCP. Cross-sectional bandwidth is 200Gbps (slight over-subscription).

We run the workload in our Linux machines with and without EQDS, and measure performance using `ping`, `iperf` and `iperf3` for UDP tests. Our kernel and DPDK stacks interoperate and at 25Gbps have similar performance, so we omit a performance breakdown.

Our T2 (RDMA) testbed has six endpoints, each with a 2.1GHz Intel Xeon E5-2620 v2 CPU. The hosts are connected to an NVIDIA Spectrum SN3700 switch, configured using loopback cables as a 2-tier Clos topology with 40 Gbps bisectional bandwidth. All links are configured to 10 Gbps with 4 KiB MTU. Each of six ports of the switch is connected either to one of three dual-port 8-core NVIDIA BlueField-2 Smart NIC (two of which clock at 2.5 GHz and one at 2 GHz), or to an NVIDIA Mellanox ConnectX-4 Lx.

We implement trimming in the SN3700 by mirroring and truncating dropped frames, then sending them to a dedicated loopback port where a P4 program redirects them back to the destination port and appropriate queue. When trimming is enabled, switch buffers are set to 60 kB.

When using ConnectX-4 Lx NICs, EQDS runs on the host CPU instead of the SmartNIC, and traffic between the host network stack and EQDS uses NIC loopback.

The baseline RDMA performance for SmartNICs is measured by configuring the SmartNICs to forward traffic between the host and the network in hardware, without going through the ARM cores. For NICs, the host network stack uses the RDMA NIC directly.
Buffer settings for TCP EQIFs. Our experiments show that TCP/IP runs smoothly over EQDS with our default settings (sending EQIFs buffer up to 100 packets per destination), but does this change with other buffer sizes? Larger buffers simply result in more EQDS sender-side buffering for TCP Cubic, and do not affect performance at all. What about smaller buffers?

When the send buffer is at least one BDP (30 packets in our testbed), all TCP variants achieve line-rate; below that the throughput depends on the congestion controller. DCTCP maintains full utilization with K=16, while BBR needs half that to reach line rate..

DCQCN parameter settings for the RDMA EQIF. Our RDMA EQIF performs flow control using the NIC's DC-QCN implementation, but it has a shorter control loop than a baseline DCQCN setup: it sends CNPs directly to the sender NIC instead of simply marking packets and waiting for the receiver to send CNPs. This allows more aggressive DCQCN parameters to be used.

We explored the DCQCN parameter space, varying the EQIF's probabilistic marking thresholds (K_{low}/K_{high}), active increase rate (R_{AI}) and rate increase/decrease timers (R_d/R_i). Our goal was to be able to stop the RDMA sender quickly during large incasts (1Mbps per sender) without dropping packets, and to be able to resume at line rate (i.e. have enough buffering) when an incast subsides (available rate is 25Gbps). The resulting parameters, shown below, are as aggressive as possible without under or overflowing the EQIF queue.

	K_{low}	K_{high}	R_d	R_i	R_{AI}
Baseline	150 kB	1500 kB	4 μsec	300 μsec	5 Mbps
EQDS(BF2)	72 kB	584 kB	4 μsec	750 μsec	5 Mbps
EQDS(Cx4)	150 kB	1500 kB	4 μsec	128 μsec	50 Mbps

Backpressure Flow Control

Abstract

Effective congestion control for data center networks is becoming increasingly challenging with a growing amount of latency-sensitive traffic, much fatter links, and extremely bursty traffic. Widely deployed algorithms, such as DCTCP and DCQCN, are still far from optimal in many plausible scenarios, particularly for tail latency. Many operators compensate by running their networks at low average utilization, dramatically increasing costs.

In this paper, we argue that we have reached the practical limits of end-to-end congestion control. Instead, we propose, implement, and evaluate a new congestion control architecture called *Backpressure Flow Control* (BFC). BFC provides per-hop per-flow flow control, but with bounded state, constant-time switch operations, and careful use of buffers and queues. We demonstrate BFC's feasibility by implementing it on Tofino2, a state-of-the-art P4-based programmable hardware switch. In simulation, we show that BFC achieves near optimal throughput and tail latency behavior even under challenging conditions such as high network load and incast cross traffic. Compared to deployed end-to-end schemes, BFC achieves 2.3 - 60× lower tail latency for short flows and 1.6 - 5× better average completion time for long flows.

1 INTRODUCTION

Single and multi-tenant data centers have become one of the largest and fastest growing segments of the computer industry. Data centers are increasingly dominating the market for all types of high-end computing, including enterprise services, parallel computing, large scale data analysis, fault-tolerant middleboxes, and global distributed applications [10, 27, 47]. These workloads place enormous pressure on the data center network to deliver, at low cost, ever faster throughput with low tail latency even for highly bursty traffic [24, 63].

Although details vary, almost all data center networks today use a combination of endpoint congestion control, FIFO queues at switches, and end-to-end feedback of congestion signals like delay or explicit switch state to the endpoint control loop.[1] As link speeds continue to increase, however, the design of the control loop becomes more difficult. First, more traffic fits within a single round trip, making it more

difficult to use feedback effectively. Second, traffic becomes increasingly bursty, so that network load is not a stable property except over very short time scales. And third, switch buffer capacity is not keeping up with increasing link speeds (Fig. 1), making it even more challenging to handle traffic bursts. Most network operators run their networks at very low average load, throttle long flows at far below network capacity, and even then see significant congestion loss.

Instead, we propose a different approach. The key challenge for data center networks, in our view, is to efficiently allocate buffer space at congested network switches. This becomes easier and simpler when control actions are taken per flow and per hop, rather than end-to-end. Despite its advantages, per-hop per-flow flow control appears to require per-flow state at each switch, even for quiescent flows [11,41], something that is not practical at data center scale.

Our primary contribution is to show that per-hop per-flow flow control can be *approximated* with a limited amount of switch state and modest number of switch queues, using only simple constant-time switch operations on a modern programmable switch. Instead of all flows, we only need state and dedicated queues for *active flows*—those flows with queued packets. We show that, with switch-level fair queueing or shortest flow scheduling, the number of active flows is modest for typical data center workloads, even in the tail of the distribution. The tradeoff is that performance can degrade when the number of active flows exceeds the number of queues. In practice, we advocate combining per-hop flow control with end-to-end congestion control to avoid pathological behavior. However, to better illustrate the benefits and limitations of our approach, our description and experiments focus on comparing pure per-hop control with pure end-to-end control.

We have implemented our approach, *Backpressure Flow Control (BFC)*, on Tofino2 a state-of-the-art P4-based programmable switch ASIC supporting 12.8 Tbps of switching capacity [33]. Tofino2 has 32-128 independently pausable queues at each output port. Our implementation uses less than 10% of the dedicated stateful memory on Tofino2. All per-packet operations are implemented entirely in the dataplane; BFC runs at full switch capacity.

To evaluate performance, we run large-scale ns-3 [4] simulations using synthetic traces drawn to be consistent with measured workloads from Google and Facebook data centers [49] on an oversubscribed multi-level Clos network

---

[1]We refer to schemes that rely on feedback signals delayed by an entire round-trip-time as *end-to-end* schemes, to contrast them with hop-by-hop mechanisms.

topology. We synthetically add incast to these workloads to represent a challenging scenario for both end-to-end and per-hop approaches. We consider both throughput and tail latency performance for short, medium, and long flows.

For our simulated workloads, BFC improves both latency for short flows and throughput for long flows. Compared to a wide set of deployed end-to-end systems, including DCTCP [8], DCQCN [65], and HPCC [43], BFC achieves 2.3 - 60× better tail flow completion times (FCTs) for short flows, and 1.6 - 5× better average performance for long flows. ExpressPass [22] achieves 35% better short flow tail latency, but 17× worse average case performance for long flows. We also show that BFC performs close to an idealized fair queueing system with unbounded buffers and switch queues, but with limited queues and far smaller buffers. BFC can be combined with other switch scheduling algorithms such as priority scheduling among traffic classes. Unlike other receiver-driven schemes like Homa [49], BFC does not assume knowledge of flow sizes and does not rely on packet spraying (which is difficult to deploy in practice). With packet spraying, Homa outperforms BFC, but without it we show BFC outperforms Homa and can enforce shortest remaining flow first scheduling more accurately.

Our specific contributions are:

- A discussion of the fundamental limits of end-to-end congestion control for high bandwidth data center networks.
- A practical protocol for per-hop per-flow flow control, called BFC, that uses a small, constant amount of state and limited number of switch queues to achieve near-optimal tail-latency performance for typical data center workloads.
- An implementation and proof-of-concept evaluation of BFC on a commercial switch. To our knowledge, this is the first implementation of a per-hop per-flow flow control scheme for a multi-Tbps switch.

2 MOTIVATION

Over the last decade, researchers and data center operators have proposed a variety of congestion control algorithms for data centers, including DCTCP [8], Timely [48], Swift [40], DCQCN [65], and HPCC [43]. The primary goals of these protocols are to achieve high throughput, low tail packet delay, and high resilience to bursts and incast traffic patterns. Operationally, these protocols rely on *end-to-end* feedback loops, with senders adjusting their rates based on congestion feedback signals echoed by the receivers. Irrespective of the type of signal (e.g., ECN marks, multi-bit INT information [36, 43], delay), the feedback delay for these schemes is a network round-trip time (RTT). This delay has an important role in the performance of end-to-end schemes. In particular, senders require at least one RTT to obtain feedback, and therefore face a hard tradeoff in deciding the starting rate of a flow. They can either start at a high rate and risk causing congestion, or start at a low rate and risk
Figure 1: Hardware trends for top-of-the-line data center switches from Broadcom. Switch capacity and link speed have been growing rapidly, but buffer size is not keeping up with increases in switch capacity.

under-utilizing the network. Moreover, even after receiving feedback, senders can struggle to determine the right rate if the state of the network (e.g., link utilization and queuing delay) changes quickly compared to the RTT.

We argue that three trends are making these problems worse over time, and will make it increasingly difficult to achieve good performance with end-to-end protocols.

Trend 1: Rapidly increasing link speed. Fig. 1 shows the switch capacity of top-of-the-line data center switches manufactured by Broadcom [20, 50, 61]. Switch capacity and link speeds have increased by a factor of 10 over the past six years with no signs of stopping.

Trend 2: Most flows are short. Fig. 2 shows the byte-weighted cumulative distribution of flow sizes for three industry data center workloads [49]: (1) All applications in a Google data center, (2) Hadoop cluster in a Facebook center, and (3) a WebSearch workload. Each point is the fraction of all bytes sent that belong to flows smaller than a threshold for that workload. For example, for the Google workload, flows that are shorter than 100 KB represent nearly half of all bytes. As link speed increases, a growing fraction of traffic belongs to flows that complete quickly relative to the RTT. For example, most Facebook Hadoop traffic is likely to fit within one round trip within the next decade. While some have argued that data center flows are increasing in size [6], the trend is arguably in the opposite direction with the growing use of RDMA for fine-grained remote memory access.

Trend 3: Buffer size is not scaling with switch capacity. Fig. 1 shows that the total switch buffer size relative to its capacity has decreased by almost a factor of 2 (from $75\,\mu s$ to $40\,\mu s$) over the past six years. With smaller buffers relative to link speed, buffers now fill up more quickly, making it more difficult for end-to-end congestion control to manage those buffers.

2.1 Limits of End-to-End Congestion Control

This combination — very fast links, short flows, and inadequate buffers — creates the perfect storm for end-to-end congestion control protocols. Flows that complete within one or a few RTTs (which constitute an increasingly larger fraction of traffic) either receive no feedback, or last for so few feedback cycles that they cannot find the correct
Figure 2: Cumulative bytes contributed by different flow sizes for three different industry workloads. The three vertical lines show the BDP for a 10 Gbps, 40 Gbps, and 100 Gbps network, assuming a $12\,\mu s$ RTT.

Figure 3: Mean percent change in fair-share rate as a function of workload, delay, and bandwidth.

Scheme	Throughput (%)	99% Queuing Delay (μs)
BFC	37.3	1.2
HPCC	22.9	23.9
DCQCN	10.0	30.4

Table 1: For a shared 100 Gbps link, BFC achieves close to ideal throughput (40%) for the long flow, with low tail queuing delay.

rate [34]. For longer flows, the rapid arrival and departure of cross-traffic creates significant fluctuations in available bandwidth at RTT timescales, making it difficult to find the correct rate. The result is loss of throughput and large queue buildup. Insufficient switch buffering further exacerbates these problems, leading to packet drops or link-level pause events (PFC [62]) that spread congestion upstream.

To understand these issues, we consider an experiment with a long-lived flow competing on a single link against cross-traffic derived from the Google, Facebook, and WebSearch workloads. We repeat the experiment at 10, 40, and 100 Gbps, with the average load of the cross-traffic flows set to be 60% of the link capacity in each case. Fig. 3 plots the relative change in the fair-share rate of the long-lived flow over different time intervals.[2] Congestion control protocols struggle to track the fair-share rate when it varies significantly over their feedback delay (typically an RTT). As link speeds increase or flows become shorter, the fair-share rate changes more rapidly (since flows arrive and finish more quickly), and hence congestion control becomes more difficult.

Table 1 considers one configuration in detail, with a single long flow sharing a 100 Gbps link with cross-traffic drawn from the Facebook distribution at 60% average load. The

---

[2]The fair-share rate ($f(t)$) for a link of capacity C shared by $N(t)$ flows is $C/N(t)$. The relative change in $f(t)$ over time interval I is given by $\left| \frac{f(t+I)-f(t)}{f(t)} \right|$.

minimum RTT (hence, feedback delay) is $8\,\mu s$. We consider both the single packet (99th percentile) queuing delay and throughput for the long flow, for our approach (BFC) and two end-to-end protocols (DCQCN and HPCC). BFC is able to achieve close to the maximum possible throughput for the long-lived flow (40%) with low tail delay, while the end-to-end protocols fall short in both respects.

2.2 Existing Solutions are Insufficient

There are several existing solutions that go beyond end-to-end congestion control. We briefly discuss the most prominent of these approaches and why they are insufficient to deal with the challenges described above.

Priority flow control (PFC). One approach to handling increased buffer occupancy would be to use PFC, a hop-by-hop flow control mechanism.[3] With PFC, if the packets from a particular input port start building up at a congested switch (past a configurable threshold), the switch sends a "pause" frame upstream, stopping that input from sending more traffic until the switch has a chance to drain stored packets. This prevents switch buffers from being overrun. Unfortunately, PFC has a side effect: head-of-line (HoL) blocking [65]. For example, incast traffic to a single server can cause PFC pause frames to be sent one hop upstream towards the source of the traffic. This stops *all* the traffic traversing the paused link, even those flows that are destined to other uncongested egress ports. These flows will be delayed until the packets at the congested port can be drained. Worse, as packets queue up behind a PFC, additional PFC pause frames can be triggered at upstream hops, widening the scope of HoL blocking.

Switch scheduling. Several efforts use switch scheduling to overcome the negative side-effects of elephant flows on the latency of short flows. These proposals range from approximations of fair queuing (e.g., Stochastic Fair Queuing [46], Approximate Fair Queuing [53]) to scheduling policies that prioritize short flows (e.g., pFabric [9], QJump [28], Homa [49]). Our work is orthogonal to the choice of switch scheduling policy, and we present results with priority scheduling and shortest flow first. Scheduling by itself does nothing to reduce buffer occupancy; buffers can fill, causing packet drops or HoL blocking, regardless of scheduling.

Receiver-based congestion control. Because sender-based congestion control schemes generally perform poorly on incast workloads, some researchers have proposed shifting to a scheme where the receiver prevents congestion by explicitly allocating credits to senders for sending traffic. Three examples are NDP [30], pHost [25] and Homa [49]. BFC makes fewer assumptions than these approaches. Homa, for example, assumes knowledge of the flow size distribution and flow length, so that it can assign flows to near-optimal priority queues; this is unavailable with today's TCP socket interface

---

[3]For simplicity, we focus on the case where there is congestion among the traffic at a particular priority level.

and not all applications know flow lengths in advance [13,59]. Homa uses packet spraying to achieve better load balancing, so that congestion primarily occurs at the last hop, where the receiver has complete visibility. However, congestion-free operation of the core is difficult to engineer for widely deployed oversubscribed and asymmetric networks [54,64,66]. Packet spraying can also cause packet reordering, which is incompatible with high-speed end host software and hardware packet handling [35,45]. Other proposals suggest collecting credits generated by a flow's receiver (congestion-controlled by all switches on the flow's path) before sending [22]; at high link speeds, the network state changes rapidly over the feedback delay, making it difficult for the receiver to determine the right rate for credits, similar to sender-based protocols.

2.3 Revisiting Per-hop, Per-Flow Flow Control

Our approach is inspired by work in the early 90s on hop-by-hop credit-based flow control for managing gigabit ATM networks [11,41]. Credit-based flow control was also introduced by multiprocessor hardware designs of the same era [19,38,42]. In these systems, each switch methodically tracks its buffer space, granting permission to send at an upstream switch if and only if there is room in its buffer. In ATM, packets of different flows are buffered in separate queues and are scheduled according to the flows' service requirements. The result is a network that has no congestion loss by design.

An ideal realization of such a per-hop, per-flow flow control scheme has several desirable properties:

(1) Fast reaction: When a flow starts experiencing congestion at a switch, the upstream switch can reduce its rate within a 1-Hop RTT, instead of the end-to-end RTT that it takes for standard congestion control schemes. Likewise, when capacity becomes available at a switch, the upstream switch can increase its rate within a 1-Hop RTT (provided the upstream switch has packets from that flow). Assuming a hardware implementation, the 1-hop RTT consists of the propagation latency and the switch pipeline latency — typically 1-2 μs.[4] This is substantially smaller than the typical end-to-end RTT in data centers (e.g., 10-20 μs), which in addition to multiple switch hops includes the latency at the endpoints.

(2) Buffer pooling: During traffic bursts, a per-hop per-flow flow control mechanism throttles traffic upstream from the bottleneck. This enables the bottleneck switch to tap into the buffers of its upstream neighbors, thereby significantly increasing the ability of the network to absorb bursts.

(3) No HoL blocking: Unlike PFC, there is no HoL blocking or congestion spreading with per-hop per-flow flow control, because switches isolate flows in different queues and perform flow control for each of them separately.

(4) Simple control actions: Flow control decisions in a per-hop per-flow flow control system are simpler to design and

reason about than end-to-end congestion control algorithms because: *(i)* whether to send or pause a flow at a switch depends only on feedback from the immediate next-hop switch (as opposed to multiple potential points of congestion with end-to-end schemes), *(ii)* concerns like fairness are dealt with trivially by scheduling flows at each switch, and therefore flow control can focus exclusively on the simpler task of managing buffer occupancy and ensuring high utilization.

Despite these compelling properties, per-hop per-flow flow control schemes have not been widely deployed, in part because of their high implementation complexity and resource requirements. ATM schemes require per-connection state and large buffers, which are not feasible in today's data center switches. We observe, however, that per-connection switch state is not actually required. Indeed, much of the time, per-connection state is for flows that have no packets queued at the switch, and therefore don't need to be flow controlled.

We define an *active flow* to be a flow with one or more packets queued at the switch. A result of queuing theory is that the number of active flows is surprisingly small for a switch using fair queuing [37,39]. In particular, for an M/G/1-PS (Processor Sharing) queue with Poisson flow arrivals operating at average load $\rho < 1$, the number of active flows has a geometric distribution with mean $\frac{\rho}{1-\rho}$, independent of the link speed or the flow size distribution. Even at load $\rho = 0.9$, the expected number of active flows is only 9. The intuition behind this fact is that a fair queued switch will tend to process short flows quickly, completing them and keeping the number of active flows small.

Data center network workloads are often more bursty than Poisson, leading to longer queues and more active flows. However, the basic principle still holds. Fig. 4 shows the cumulative distribution of the number of active flows for a single bottleneck link operating at different loads and link speeds, using the Google flow size distribution and (bursty) log-normal flow inter-arrival times. The upper graph assumes fair queuing and includes a vertical bar for the number of queues per port on Tofino2. At 100 Gbps, the number of active flows significantly exceeds the number of queues only for loads above 85%, and then only modestly; importantly, the distribution is invariant to link speed, and the trend is for faster links to have more queues. The result holds even more strongly with shortest remaining flow first (SRF) scheduling. By contrast, with FIFO queuing, even a single long flow can cause a large number of small flows to back up behind it, and therefore the number of active flows is much larger.

3 DESIGN

Our goal is to design a practical system for per-hop, per-flow flow control for data center networks. We first describe the constraints on our design (§3.1). We then sketch a plausible strawman proposal that surprisingly turns out to not work well at all (§3.2), and we use that as motivation for our design (§3.3).

---

[4]For example, a 100 m cable has a propagation latency of 500 ns, and a typical data center switch has a pipeline latency around 500 ns [15,20].

Figure 5: Logical switch components in per-hop, per-flow flow control.

3.1 Design Constraints

Fig. 5 shows the basic components of a per-hop, per-flow flow control scheme (per port). (1) *Mapping to physical queues:* When a packet arrives at the switch, the switch routes the packet to an egress port and maps it to a FIFO queue at that port. This assignment of flows to queues must be consistent, that is, respect packet ordering. (2) *Backpressure module:* Based on queue occupancy, the switch generates backpressure feedback for some flows and sends it upstream. (3) *Scheduler:* The scheduler at each egress port forwards packets from queues while respecting backpressure feedback from the downstream switch.

ATM per-hop per-flow flow control systems [11, 41] roughly followed this architecture, but they would be impractical for modern data centers. First, they assumed per-flow queues and state, but modern switches have a limited number of queues per egress port [17,53] and modest amounts of table memory [18,23]. In particular, it is not possible to maintain switch state for all live connections. Second, earlier schemes did not attempt to minimize buffer occupancy. Instead, they sent backpressure feedback only when the switch was about to run out of buffers. On a buffer-constrained switch, this can result in buffer exhaustion — buffers held by straggler flows can prevent other flows from using those buffers at a later time.

Hardware assumptions. Modern data center switches have made strides towards greater flexibility [12,56], but they are not infinitely malleable and have real resource constraints. We make the following assumptions based on the capabilities of Tofino2.

1. We assume the switch is programmable and supports stateful operations.Tofino2 can maintain millions of register entries, and supports simple constant-time per-packet operations to update the state at line rate [55].
2. The switch has a limited number of FIFO queues per egress port, meaning that flows must be multiplexed onto queues. Tofino2 has 32/128 queues per 100/400G port. The assignment of flows to queues is programmable. The scheduler can use deficit round-robin or priorities among queues, but packets within a queue are forwarded in FIFO order.
3. Each queue can be independently paused and resumed without slowing down forwarding from other queues. When we pause a queue, that pauses *all* of the flows assigned to that queue. The switch can pause/resume each queue directly within the dataplane.

3.2 A Strawman Proposal

We originally thought stochastic fair queuing [46] with per-queue backpressure might meet our goals: use a hash function on the flow header to consistently assign the packets of each flow to a randomly-chosen FIFO queue at its egress port, and pause a queue whenever its buffer exceeds the 1-hop bandwidth-delay product (BDP). For simplicity, use the same hash function at each switch.

This strawman needs only a small amount of state for generating the backpressure feedback and no state for queue assignment. However, with even a modest number of active flows, the birthday paradox implies that there is a significant chance that any specific flow will land in an already-occupied FIFO queue. These collisions hurt latency for two reasons: (1) The packets for the flow will be delayed behind unrelated packets from other flows; for example, a short flow may land behind a long flow. (2) Queue sharing can cause HoL blocking. If a particular flow is paused (because it is congested downstream), all flows sharing the same queue will be delayed. To prevent collisions from affecting tail latency performance, the strawman requires significantly more queues than active flows. For example, at an egress port with n active flows, to achieve fewer than 1% collisions, we would need roughly $100n$ queues.

3.3 Backpressure Flow Control (BFC)

Our design achieves the following properties:

Minimal HoL blocking: We assign flows to queues dynamically. As long as the number of active flows at an egress is less than the number of queues, (with high probability) no two flows share a queue and there is no HoL blocking. When a new flow arrives at the switch, it is assigned to an empty queue if one is available, sharing queues only if all are in use.

Low buffering and high utilization: BFC pauses a flow at the upstream when the queue occupancy exceeds a small threshold. BFC's pause threshold is set aggressively to

reduce buffering. With coarse pausing like PFC, pausing aggressively hurts utilization, but BFC only pauses those flows causing congestion (except when collisions occur). The remaining flows at the upstream can continue transmitting, avoiding under-utilization.

Hardware feasibility: BFC does not require per-flow state, and instead uses an amount of memory proportional to the number of physical queues in the switch. To allow efficient lookup of the state associated with a flow, the state is stored in a flow table, an array indexed using a hash of the flow identifier. The size of this array is set in proportion to the number of physical queues. In our Tofino2 implementation, it consumes less than 10% of the dedicated stateful memory. Critically, the mechanism for generating backpressure and reacting to it is simple and the associated operations can be implemented entirely in the dataplane at line rate.

Generality: BFC does not make assumptions about the network topology or where congestion can occur, and does not require packet spraying like NDP [30] or Homa [49]. Furthermore, it does not assume knowledge of flow sizes or deadlines. Such information can be incorporated into BFC's design to improve small flow performance (see App. A.2), at a cost in deployability.

Idempotent state: Because fiber packets can be corrupted in flight [66], BFC ensures that pause and resume state is maintained idempotently, in a manner resilient to packet loss.

3.3.1 Assigning flows to queues

To minimize sharing of queues and HoL blocking, we dynamically assign flows to empty queues. As long as the flow is active (has packets queued at the switch), subsequent packets for that flow will be placed into the same FIFO queue. Each flow has a unique 5-tuple of the source and destination addresses, port numbers, and protocol; we call this the flow identifier (FID). BFC uses the hash of the FID to track a flow's queue assignment. To simplify locating an empty queue, BFC maintains a bit map of empty queues. When the last packet in a queue is scheduled, BFC resets the corresponding bit for that queue.

With dynamic queue assignment, a flow can be assigned to different queues at different switches. To pause a flow, BFC pauses the queue the flow came from at the upstream switch (called the upstream queue). The pause applies to all flows sharing the same upstream queue with the paused flow. We describe the pause mechanism in detail in §3.3.2. The packet scheduler uses deficit round robin to implement fair queuing among the queues that are not paused.

Since there is a limited number of queues, it is possible that all queues have been allocated when a new flow arrives, at which point HoL blocking is unavoidable. For hardware simplicity, we assign the flow to a random queue in this case. Packets assigned to the same queue are scheduled in FIFO order. The number of active flows is usually small (§2.3), but in certain settings, such as incast, it can exceed the number of queues. BFC's behavior is similar to stochastic fair queuing in such scenarios in that it incurs HoL blocking. BFC still outperforms existing protocols like DCQCN and HPCC except in the most extreme cases (see App. A.1). Even during a large scale incast, BFC can leverage the large number of upstream queues feeding traffic to a bottleneck switch to (1) absorb larger bursts, and (2) limit congestion spreading. In particular, when flows involved in an incast are spread among multiple upstream ports, BFC assigns these flows to separate queues at those ports. As long as the total number of flows does not exceed the total number of queues across *all* of the upstream ports, BFC will not incur HoL blocking at the upstream switches. As the size of the network increases and the fan-in to each switch gets larger, there will be even more queues at the upstream switches to absorb an incast, further reducing congestion spreading.

Mechanism: To keep track of queue assignment, BFC maintains an array indexed by the egress port of a flow and the hash of the FID. All flows that map to the same index are assigned to the same queue. We maintain the following state per entry: the physical queue assignment (`qAssignment`), and the number of packets in the queue from the flows mapped to this entry (`size`). The pseudocode is as follows (we defer switch-specific implementation issues to §6.1):

```
On Enqueue(packet):
    key = <packet.egressPort, hash(packet.FID)>
    if flowTable[key].size == 0:
        reassignQueue = True:
    flowTable[key].size += 1
    if reassignQueue:
        if empty q available at packet.egressPort:
            qAssignment = emptyQ
        else:
            qAssignment = randomQ
        flowTable[key].qAssignment = qAssignment
    packet.qAssignment = flowTable[key].qAssignment

On Dequeue(packet):
    key = <packet.egressPort, hash(packet.FID)>
    flowTable[key].size -= 1
```

In the flow table, if two flows map to the same index they will use the same queue (collision). Since flows going through different egress ports cannot use the same queue, the index also includes the egress port. Index collisions in the flow table can hurt performance. These collisions decrease with the size of the table, but the flow table cannot be arbitrarily large as the switch has a limited stateful memory. In our design, we set the size of the flow table to $100 \times$ the number of queues in the switch. This ensures that if the number of flows at an egress port is less than the number of queues, then the probability of index collisions is less than 1%. If the number of flows exceeds the number of queues, then the index collisions do not matter as there will be collisions in the physical queues regardless. Tofino2 has 4096 queues in aggregate, and hence the size of the flow table is 409,600 entries, which is less than 10% of the switch's dedicated stateful memory.

While using an array is not memory efficient, accessing state involves simple operations. Existing solutions for maintaining flow state either involve slower control plane operations, or are more complex [14, 51]. In the future, if the number of queues increases substantially, we can use these solutions for the flow table; however at the moment, the additional complexity is unnecessary.

3.3.2 Backpressure mechanism

BFC pauses a flow if the occupancy of the queue assigned to that flow exceeds the pause threshold Th. To pause/resume a flow, the switch could signal the flow ID to the upstream switch, which can then pause/resume the queue associated with the flow. While this solution is possible in principle, it is difficult to implement on today's programmable switches. The challenge is that, on receiving a pause, the upstream switch needs to perform a lookup to find the queue assigned to the flow and some additional bookkeeping to deal with cases when a queue has packets from multiple flows (some of which might be paused and some not).

We take a different approach. Switches directly signal to the upstream device to pause/resume a specific queue. Each upstream switch/source NIC inserts its local queue number in a special header field called upstreamQ. The downstream switch uses this information to pause the queue at the upstream.

Mechanism: Recall that, in general, multiple flows can share a queue in rare cases. This has two implications. First, we track the queue length (and not just the flowTable.size) and use that to determine if the flow's upstream queue should be paused. Second, each upstream queue can, in general, have flows sending packets to multiple queues at multiple egresses. We pause an upstream queue if *any* of its flows are assigned a congested queue, and we resume when *none* of its flows have packets at a congested queue (as measured at the time the packet arrived at the switch).

We monitor this using a Pause Counter, an array indexed by the ingress port and the upstreamQ of a packet. The upstream queue is paused if and only if its Pause Counter at the downstream switch is non-zero. On enqueue of a packet, if its flow is assigned a queue that exceeds the pause threshold, we increment the pause counter at that index by 1. When this packet (the one that exceeded Th) leaves the switch we decrement the counter by 1. Regardless of the number of flows assigned to the upstreamQ, it will be resumed only once all of its packets that exceeded the pause threshold (when the packet arrived) have left the switch.

```
On Enqueue(packet):
    key = <packet.ingressPort, packet.upstreamQ>
    if packet.qAssignment.qLength > Th:
        packet.metadata.counterIncr = True
        pauseCounter[key] += 1
        if pauseCounter[key] == 1:
            //Pause the queue at upstream
            sendPause(key)
```

```
On Dequeue(packet):
    key = <packet.ingressPort, packet.upstreamQ>
    if packet.metadata.counterIncr == True:
        pauseCounter[key] -= 1
        if pauseCounter[key] == 0:
            //Resume the queue at upstream
            sendResume(key)
```

To minimize bandwidth consumed in sending pause/resumes, we only send a pause packet when the pause counter for an index goes from 0 to 1, and a resume packet when it goes from 1 to 0. For reliability against pause/resume packets being dropped, we also periodically send a bitmap of the queues that should be paused at the upstream (using the pause counter). Additionally, the switch uses a high priority queue for processing the pause/resume packets. This reduces the number of queues available for dynamic queue assignment by 1, but it eliminates performance degradation due to delayed pause/resume packets.

The memory required for the pause counter is small compared to the flow table. For example, if each upstream switch has 128 queues per egress port, then for a 32-port downstream switch, the pause counter is 4096 entries.

Pause threshold. BFC treats any queue buildup as a sign of congestion. BFC sets the pause threshold Th to 1-Hop BDP at the queue drain rate. Let N_{active} be the number of *active queues* at an egress, i.e. queues with data to transmit that are not paused, $HRTT$ be the 1-Hop RTT to the upstream, and μ be the port capacity. Assuming fair queuing as the scheduling policy, the average drain rate for a queue at the egress is μ/N_{active}. The pause threshold Th is thus given by $(HRTT) \cdot (\mu/N_{active})$. When the number of active queues increases, Th decreases. In asymmetric topologies, egress ports can have different link speeds; as a result, we calculate a different pause threshold for every egress based on its speed. Similarly, ingress ports can have different 1-Hop RTTs. Since a queue can have packets from different ingresses, we use the max of $HRTT$ across all the ingresses to calculate Th. We use a pre-configured match-action table indexed with N_{active} and μ to compute Th.

BFC does not guarantee that a flow will never run out of packets due to pausing. First, a flow can be paused unnecessarily if it is sharing its upstream queue with other paused flows. Second, a switch only resumes an upstream queue once all its packets (that exceeded the pause threshold when they arrived) have left the downstream switch. Since the resume takes an $HRTT$ to take effect, a flow can run out of packets at the downstream switch for an $HRTT$, potentially hurting utilization. However, this scenario is unlikely — a pause only occurs when a queue builds up, typically because multiple flows are competing for the same egress port. In this case, the other flows at the egress will have packets to occupy the link, preventing under-utilization.

We might reduce the (small) chance of under-utilization by resuming the upstream queue earlier, for example, when a flow's queue at the downstream drops below Th, or more precisely, when *every* queue (with a flow from the same

upstream queue) drops below Th. Achieving this would require extra bookkeeping, complicating the design.

Increasing the pause threshold would reduce the number of pause/resumes generated, but only at the expense of increased buffering (Fig. 7). In App. C, we analyze the impact of Th on under-utilization and peak buffer occupancy in a simple model, and we show that a flow runs out of packets at most 20% of the time when Th is set to 1-hop BDP. Our evaluation results show that BFC achieves much better throughput than this worst case in practice (Table 1, §6).

Sticky queue assignment: Using `upstreamQ` for pausing flows poses a challenge. Since a switch does not know the current queue assignment of a flow at the upstream, it uses the `upstreamQ` conveyed by the last packet of the flow to pause a queue. However, if a flow runs out of packets at the upstream switch (e.g., because it was bottlenecked at the downstream switch but not the upstream), then its queue assignment may change for subsequent packets, causing it to temporarily evade the pause signal sent by the downstream switch. Such a flow will be paused again when the downstream receives packets with the new `upstreamQ`. The old queue will likewise be unpaused when its last packet (that exceeded Th) departs the downstream switch.

To reduce the impact of such queue assignment changes, we add a timestamp to the flow table state, updated whenever a packet is enqueued or dequeued. A new queue assignment only happens if the `size` value in the flow table is 0, and the timestamp is older than a "sticky threshold" (i.e., the entry in the flow table has had no packets in the switch for at least this threshold). Since with BFC's backpressure mechanism a flow can run out of packets for an $HRTT$, we set the sticky threshold to a small multiple of $HRTT$ (2 $HRTT$).

While sticky queue assignments reduce the chance that a backlogged flow will change queues, it doesn't completely eliminate it (e.g., packets from the same flow may arrive slower than this interval due to an earlier bottleneck). Such situations are rare, and we found that BFC performs nearly identically to an ideal (but impractical) variant that pauses flows directly using the flow ID without sticky queue assignments.

4   TOFINO2 IMPLEMENTATION

We implemented BFC in Tofino2, a to-be-released P4-based programmable switch ASIC with a Reconfigurable Match Table (RMT) architecture [17]. A packet in Tofino2 first traverses the ingress pipeline, followed by the traffic manager (TM) and finally the egress pipeline. Tofino2 has four ingress and four egress RMT pipelines. Each pipeline has multiple stages, each capable of doing stateful packet operations. Ingress/egress ports are statically assigned to pipelines.

Bookkeeping: The flow table and pause counter are both maintained in the ingress pipeline. The flow table contains three values for each entry and is thus implemented as three separate register arrays (one for each value), updated one after the other.

Multiple pipelines: The flow table is *split* across the four ingress pipelines, and the size of the table in each ingress pipeline is 25 $\times$ the number of queues. During normal operation, packets of an active flow arrive at a single ingress pipeline (same ingress port). Since the state for a flow only needs to be accessed in a single pipeline, we can split the flow table. However, splitting can marginally increase collisions if the incoming flows are distributed unevenly among the ingress pipelines. Similarly, the pause counter is split among the ingress pipelines. An ingress pipeline contains the pause counter entries corresponding to its own ingress ports.

Gathering queue depth information: We need queue depth information in the ingress pipeline for pausing and dynamic queue assignment. Tofino2 has an inbuilt feature tailored for this task. The TM can communicate the queue depth information for all the queues in the switch to all the ingress pipelines without consuming any additional ingress cycles or bandwidth. The bitmap of empty queues is periodically updated with this data, with a different rotating starting point per pipeline to avoid new flows from being assigned to the same empty queue.

Communicating from egress to ingress pipeline: The enqueue operations described earlier are executed in the ingress pipeline when a packet arrives. Dequeue operations should happen at the egress but the bookkeeping data structures are at the ingress. To solve this, in the egress pipeline, we mirror packets as they exit and recirculate the header of the mirrored packet back to the ingress pipeline it came from. The dequeue operations are executed on the recirculated packet header.

Recirculating packets involves two constraints. First, the switch has dedicated internal links for recirculation, but the recirculation bandwidth is limited to 12% of the entire switch capacity. Second, the recirculated packet consumes an additional ingress cycle. The switch has a cap on the number of packets it can process every second (pps capacity).

Most workloads have an average packet size greater than 500 bytes [16], and Tofino2 is designed with enough spare capacity in bandwidth and pps to handle header recirculation for every packet for those workloads (with room to spare). If the average packet size is much smaller, we can reduce recirculations by sampling packets for recirculation (described in App. A.8).

Recirculation is not fundamental to BFC. For example, Tofino2 has native support for PFC bookkeeping in the TM. Likewise, if BFC bookkeeping was implemented in the TM, it would not need recirculation. Similarly, in switches with a disaggregated RMT architecture [23] where the same memory can be accessed at both the ingress and egress, there is no need for recirculation.

5 DISCUSSION

Guaranteed losslessness. BFC does not guarantee lossless-ness. In particular, a switch in BFC pauses an `upstreamQ` only after receiving a packet from it. This implies an `upstreamQ` can send packets for up to an *HRTT* to the bottleneck switch before being paused, even if the switch is congested. In certain mass incast scenarios, this might be sufficient to trigger drops. Using credits [11, 41] could address this at the cost of added complexity. We leave an investigation of such prospective variants of BFC to future work. In our evaluation with realistic switch buffer sizes, BFC never incurred drops except under a 2000-to-1 incast (§6.3) and even then only 0.007% of the packets were dropped.

Deadlocks: Pushback mechanisms like PFC have been shown to be vulnerable to deadlocks in the presence of cyclic buffer dependencies (CBD) or misbehaving NICs [29, 31]. BFC NICs do not generate any backpressure and as a result cannot cause deadlocks. Since NICs always drain, in the absence of CBD, BFC cannot have deadlocks (see App. B for a formal proof). A downstream switch in BFC *will* resume an `upstreamQ` if it drains all the packets sent by the `upstreamQ`. If a downstream is not deadlocked, it will eventually drain packets from the upstream, and as a result, the corresponding upstream cannot be deadlocked.

To prevent CBD, we can reuse prior approaches for deadlock prevention. These approaches can be classified into two categories. The first is to redesign routing protocols to avoid installing routes that might cause CBD [57, 58]. The other is to identify a subset of possible ingress/egress pairs that are provably CBD free, and only send pause/resume along those pairs [32]. For a fat-tree topology, this would allow up-down paths but not temporary loops or detour routes [44]. In BFC, we use the latter approach. Given a topology, we pre-compute a match action table indexed by the ingress and egress port, and simply elide the backpressure pause/resume signal if it is disallowed. See App. B for details.

Incremental Deployment: In a full deployment, BFC would not require end-to-end congestion control. In a partial deployment, we advocate some form of end-to-end congestion control, such as capping the number of inflight packets of a flow. A common upgrade strategy is to upgrade switches more rapidly than server NICs. If only switches and not NICs are running BFC, capping inflight packets prevents a source NIC from overrunning the buffers of the first hop switch. The same strategy can be used for upgrading one cluster's switches before the rest of the data center [64]. In our evaluation, we show incremental deployment would have some impact on buffer occupancy at the edge but minimal impact on performance (App. A.8).
Figure 6: **Testbed topology.** The colored lines show the path for different flow groups.

(a) Queue Length   (b) Under-utilization
Figure 7: **Queue length and under-utilization.** 2 flows are competing at a 100 Gbps link. Cell size is 176 bytes. BFC achieves high utilization and low buffering.

6 EVALUATION

We present a proof-of-concept evaluation of our Tofino2 implementation. To compare performance of BFC against existing schemes, we perform large scale ns-3 [4] simulations.

6.1 Tofino2 evaluation

Testbed: For evaluation, we were able to gain remote access to a Tofino2 switch. Using a single switch, we created a simple multi-switch topology (Fig. 6) by looping back packets from the egress port back into the switch. All the ports are 100 Gbps, each port has 16 queues.[5] The experiments include three groups of flows.

- Sender Group 1 → Switch 1 → Switch 2 → Receiver 1.
- Sender Group 2 → Switch 1 → Switch 2 → Receiver 2.
- Sender Group 3 → Switch 3 → Switch 2 → Receiver 2.

To generate traffic we use the on-chip packet generator with no end-to-end congestion control.

Low buffering, high utilization: Fig. 7a shows the queue length for a flow when two flows are competing at a link (a group 2 flow is competing with a group 3 flow at the switch 2 → receiver 2 link). The pause threshold is shown as a horizontal black line. BFC's pausing mechanism is able to limit the queue length near the pause threshold (*Th*). The overshoot from *Th* is for two reasons. First, it takes an *HRTT* for the pause to take effect. Second, Tofino2 has small hardware queues after the egress pipeline, and a pause from the downstream cannot pause packets already in these hardware queues.

Notice that the queue length goes to 0 temporarily. Recall that a downstream switch only resumes the `upstreamQ`

---

[5]For 100 Gbps ports, Tofino2 has 32 queues, but in loopback mode only 16 queues are available.
Figure 8: **Congestion spreading.** Dynamic queue assignment reduces HoL blocking, improving FCTs on average and at the tail.

when it has drained all the packets from the `upstreamQ` that exceeded Th. As a result, a flow at the downstream can run out of packets for an $HRTT$. This can cause under-utilization when the queues for the two flows go empty simultaneously. We repeat the above experiment but vary the pause threshold. Fig. 7b shows the average queue length and the under-utilization of the congested link. With a pause threshold of 2 μs, BFC achieves close to 100% utilization with an average queue length of 15 KB.

Queue assignment and congestion spreading: We next evaluate the impact of queue assignment on HoL blocking and performance. We evaluate three different queue assignment strategies with BFC's backpressure mechanism: (1) "BFC + single": All flows are assigned to a single queue (similar to PFC); (2) "BFC + stochastic": Flows are assigned to queues using stochastic hashing; (3) "BFC + dynamic": Dynamic queue assignment as described in §3.3.1.

The setup consists of two group 1 flows, eight group 3 flows, and a number of group 2 flows varied between four to twenty. All flows are 1.5 MB in size. The experiment is designed such that for group 2 and 3 flows, the bottleneck is the switch 2 → receiver 2 link. The bottleneck for group 1 flows is the switch 1 → switch 2 link. Switch 2 will pause queues at switch 1 in response to congestion from group 2 flows. Notice that group 1 and group 2 flows are sharing the switch 1 → switch 2 link. If a group 1 flow shares a queue with a group 2 flow (a collision), the backpressure due to the group 2 flow can slow down the group 1 flow, causing HoL blocking and increasing its flow completion time (FCT) unnecessarily.

Fig. 8 shows the average FCT for group 1 flows across four runs. The whiskers correspond to one standard deviation in the FCT. BFC + single achieves the worst FCT as group 1 and 2 flows always share a queue. With stochastic assignment, the FCT is substantially lower, but the standard deviation in FCT is high. In some runs, group 1 and 2 flows don't share a queue and there is no HoL blocking. In other runs, due to the stochastic nature of assignment, they do share a queue (even when there are other empty queues), resulting in worse performance. With dynamic assignment, BFC achieves the lowest average FCT and the best tail performance. In particular, the standard deviation is close to 0 when the number of flows at the switch 1 → switch 2 link (group 1 + group 2 flows) is lower than the number of queues. In such scenarios, group 1 flows consistently incur no collisions. When the number of flows exceed the queues, collisions are

inevitable, and the standard deviation in FCT increases.

6.2 Simulation-based evaluation

We also implemented BFC in ns-3 [4]. For DCQCN we use [5], for ExpressPass we use [1], and for all other schemes we use [3].

6.2.1 Setup

Network Topology: We use a Clos topology with 128 leaf servers, 8 top of the rack (ToR) switches and 8 Spine switches (2:1 over subscription). Each Spine switch is connected to all the ToR switches, each ToR has 16 servers, and each server is connected to a single ToR. All links are 100 Gbps with a propagation delay of 1 us. The maximum end-to-end base round trip time (RTT) is 8 μs and the 1-Hop RTT is 2 μs. The switch buffer size is set to 12 MB. Relative to the ToR switch capacity of 2.4 Tbps, the ratio of buffer size to switch capacity is 40 μs, the same as Broadcom's Tomahawk3 from Fig. 1. We use an MTU of 1 KB. Unless specified otherwise, we use Go-Back-N for retransmission, flow-level ECMP for load balancing, and the standard shared buffer memory model implemented in existing switches [20].

Comparisons: *HPCC:* HPCC uses explicit link utilization information from the switches to reduce buffer occupancy and drops/PFCs at the congested switch. We use the parameters from the paper, $\eta = 0.95$ and $maxStage = 5$. The dynamic PFC threshold is set to trigger when traffic from an input port occupies more than 11% of the free buffer (as in the HPCC paper). We use the same PFC thresholds for DCQCN and DCTCP. *HPCC-PFC:* This version replaces PFC with perfect retransmission. On a packet drop, the switch informs the sender directly, which then retransmits the dropped packet. We choose this (potentially impractical) strategy to provide a bound on the performance that can be achieved using any retransmission scheme. *DCQCN:* DCQCN uses ECN bits and end-to-end control to manage buffer use at the congested switch. The ECN threshold triggers before PFC (K_{min} = 100KB and K_{max} = 400KB). *DCTCP:* The ECN threshold is same as DCQCN. Flows start at line rate to avoid degradation in FCTs from slow-start. *ExpressPass:* In ExpressPass, senders transmit data based on credits generated by the receiver. These credits are rate-limited at the switches to avoid congestion. We chose $\alpha = 0.5, w_{init} = 0.0625$ and a credit buffer size of 16 credits. The ExpressPass simulator does not follow a shared buffer model; instead it assumes dedicated per-port buffers. To eliminate drops, we supplied a high per-port buffer value of 75 MB. There is no PFC. *BFC:* We use 32 physical queues per port (consistent with Tofino2) and our flow table has 76K entries. The flow table takes 400 KB of memory. We chose per-flow fair queuing as our scheduling mechanism; all the comparison schemes strive for per-flow fairness, thus, fair queuing provides for a just comparison.

(a) FCT   (b) Buffer occupancy   (c) PFC Time

Figure 9: Google distribution with 55% load + 5% 100-1 incast. BFC tracks the ideal behavior, improves FCTs, and reduces buffer occupancy. For FCT slowdown, both the x and y axis are log scaled.

(a) FCT   (b) Buffer Occupancy   (c) Active Flows

Figure 10: FCT slowdown and buffer occupancy for Google distribution with 60% load. For all the schemes, PFC was never triggered. Part (c) shows the CDF of active flows at a port with and without incast, with the vertical bar showing the total number of queues per port.

Ideal-FQ: To understand how close BFC comes to optimal performance, we simulate ideal fair queuing with infinite buffering at each switch. The NICs cap the in-flight packets of a flow to 1 BDP. Note that infinite buffering is not realizable in practice; its role is to bound how well we could possibly do.

Sensitivity to parameters: All systems were configured to achieve full throughput for a single flow on an unloaded network. For end-to-end schemes, the choice of parameters governs the trade-off between the performance of short flows (through reduced queuing) and long flows (higher link utilization). We perform parameter sensitivity analysis for HPCC, DCTCP and ExpressPass in App. A.4.

Performance metrics: We consider three performance metrics: (1) FCT normalized to the best possible FCT for the same size flow, running at link rate (referred as the FCT slowdown); (2) Overall buffer occupancy at the switch; (3) Throughput of individual flows.

Workloads: We synthesized a trace to match the flow size distributions from the industry workloads discussed in Fig. 2: (1) Aggregated workload from all applications in a Google data center; (2) a Hadoop cluster at Facebook (FB_Hadoop). The flow arrival pattern is open-loop and follows a *bursty* log-normal inter-arrival time distribution with σ = 2.[6] For each flow arrival, the source-destination pair is derived from a uniform distribution. We consider scenarios with and without incast, different traffic load settings, and incast ratios. Since our topology is oversubscribed, on average links in the core (Spine-ToR) will be more congested than the ToR-leaf server links. In our experiments, by X% load we mean X% load on

the links in the core.

6.2.2 Performance

Fig. 9 and 10 show our principal results. The flow sizes are drawn from the Google distribution and the average load is set to 60% of the network capacity. For Fig. 9 (but not Fig. 10), 5% of the traffic (on average) is from incast flows. The incast degree is 100-to-1 and the size is 20 MB in aggregate. A new incast event starts every 500 μs. Since the best-case completion time for an incast is 1.6 ms (20 MB/100 Gbps), multiple incasts coexist simultaneously in the network. We report the FCT slowdowns at the average, 95th and 99th percentile, the tail buffer occupancy (except for ExpressPass simulations which do not follow the shared buffer model), and the fraction of time links were paused due to PFC. We report the FCT slowdowns for the incast traffic separately in App. A.12.

Out of all the schemes, DCQCN is worst on latency for small flow sizes, both at the average and the tail. Compared to DCQCN, DCTCP improves latency as it uses per-ACK feedback instead of periodic feedback via QCN. However, the frequent feedback is not enough, and the performance is far from optimal (Ideal-FQ). The problem is that both DCQCN and DCTCP are slow in responding to congestion. Since flows start at line rate, a flow can build up an entire end-to-end bandwidth-delay product (BDP) of buffering (100 KB) at the bottleneck before there is any possibility of reducing its rate. The problem is aggravated during incast events. The bottleneck switch can potentially accumulate one BDP of packets per incast flow (10 MB in aggregate for 100-to-1 incast).

Both protocols have low throughput for long flows. When capacity becomes available, a long flow may fail to ramp up quickly enough, reducing throughput and shifting its work

---

[6]Most prior work evaluates using Poisson flow arrivals [22, 49], but we use the more bursty Lognormal as it provides a more challenging case for BFC.

to busier periods where it can impact other flows. Moreover, on sudden onset of congestion, a flow may not reduce its rate fast enough, slowing short flows.

HPCC improves on DCQCN and DCTCP by using link utilization instead of ECN and a better control algorithm. Compared to DCQCN and DCTCP, HPCC reduces tail latency, tail buffer occupancy, and PFC pauses (in case of incast). Compared to BFC, however, HPCC has 5-30× worse tail latency for short flows with incast, and 2.3-3× worse without. Long flows do worse with HPCC than DCQCN and DCTCP since HPCC deliberately targets 95% utilization and very small queues to improve tail latency for short flows.

With ideal retransmission, HPCC performance improves, especially for short and medium flows. However, HPCC without PFC has higher tail buffer occupancy and suffers packet loss. Compared to BFC, overall performance is still worse for both long and short flows.

Across all systems, ExpressPass achieves the worst throughput for long flows. In ExpressPass, the receiver can generate unnecessary credits for an additional RTT before learning that a flow is finished. These credits are considered "wasted" as the sender cannot transmit packets in response, and can therefore cause link under-utilization. Credit waste and the corresponding under-utilization increase with faster link speeds and/or when the flow sizes get shorter (see §6.3 and §7 in [22]).

Ideal-FQ achieves lower latency than all the schemes, but its buffer occupancy can grow to an unfeasible level.

BFC achieves the best FCTs (both average and tail) among all the schemes. Without incast, BFC performance closely tracks optimal. With incast, incoming flows exhaust the number of physical queues, triggering HoL blocking and hurting tail latency. This effect is largest for the smallest flows at the tail. Fig. 10c shows the CDF of the number of active flows at a port. In the absence of incast, the number of active flows is smaller than the total queues 99% of the time, and collisions are rare. With incast, the number of active flows increases, causing collisions. However, the tail latency for short flows with BFC is still 5-30× better than existing schemes. BFC also improves the performance of incast flows, achieving 2× better FCTs at the tail compared to HPCC (see App. A.12).

Note that, compared to BFC and Ideal-FQ, latency for medium flows (200-1000KB) is slightly better with existing schemes. Because they slow down long flows relative to perfect fairness, medium flows have room to get through more quickly. Conversely, tail slowdown is better for long flows than medium flows with BFC and Ideal-FQ. Long flows achieve close to the long term average available bandwidth, while medium flows are more affected by transient congestion.

Another workload: We repeated the experiment in Fig. 9 and Fig. 10 with the Facebook distribution. Fig. 11 shows the 99th percentile FCT slowdown. The trends in the FCT slowdowns are similar to that of the Google distribution, except that ExpressPass performs better since it incurs fewer wasted

(a) 55% + 5% 100-1 incast   (b) 60%
Figure 11: FCT slowdown (99th percentile) for Facebook distribution with and without incast.

(a) Average FCT for long flows   (b) Tail FCT for short flows

credits (as a percentage) for the Facebook workload, which has larger flows. We omit other statistics presented earlier in the interest of space, but the trends are similar to Fig. 9 and 10. Henceforth, all the experiments use the Facebook workload.

6.3 Stress-testing BFC

In this section we stress-test BFC under high load and large incast degree. Flow arrivals follow a bursty log-normal distribution ($\sigma = 2$). We evaluate BFC under two different queue configurations: (1) 32 queues per port (BFC 32); (2) 128 queues per port (BFC 128). We show the average slowdown for long flows (> 3MB) and 99th percentile slowdown for short flows (< 3KB).

Load: Fig. 12 shows the performance as we vary the average load from 50 to 95% (without incast). HPCC only supports loads up to 70%. At higher loads, it becomes unstable (the number of outstanding flows grows without bound), in part due to the overhead of the INT header (80 B per-packet). All other schemes were stable across all load values.

At loads ≤ 80%, BFC 32 achieves both lower tail latency (Fig. 12b) for short flows and higher throughput for long flows (Fig. 12a). The tail latency for short flows is close to the perfect value of 1. At higher loads, flows remain queued at the bottleneck switch for longer periods of time, raising the likelihood that we run out of physical queues, leading to head of line blocking. This particularly hurts tail performance for short flows as they might be delayed for an extended period if they are assigned to the same queue as a long flow. At the very high load of 95%, the HoL blocking degrades tail latency substantially for BFC 32. However, it still achieves good link utilization, and the impact of collisions is limited for long flows.

Increasing the number of queues reduces collisions and the associated HoL blocking. BFC 128 achieves better tail latency for short flows at load ≥ 90%.
(a) Average FCT for long flows   (b) Tail FCT for short flows

Figure 13: Average FCT slowdown for long flows, and 99th percentile tail FCT slowdown for small flows, as a function of incast degree.
(a) FCT SlowDown   (b) Buffer Occupancy

Figure 14: FCT slowdown (99th percentile) and buffer occupancy of HPCC variants, using the setup in Fig. 11a.

Incast degree: If the size of an incast is large enough, it can exhaust physical queues and hurt performance. Fig. 13 shows the effect of varying the degree of incast on performance. The average load is 60% and includes a 5% incast. The incast size is 20 MB in aggregate, but we vary the degree of incast from 10 to 2000.

For throughput, both BFC 32 and BFC 128 perform well as long as the incast degree is moderate compared to the number of queues. Both start to degrade when the incast degree exceeds $8\times$ the number of queues per port. Till this point, BFC can leverage the FanIn from the larger number of upstream queues (and greater aggregate upstream buffer space) to keep the incast from impeding unrelated traffic. As the incast degree scales up further, BFC 32 is able to retain some of its advantage relative to HPCC and DCTCP.

For high incast degree, the tail latency for short flows becomes worse than HPCC. The tail is skewed by the few percent of small requests that happen to go to the same destination as the incast. (Across the 128 leaf servers in our setup, several servers are the target of an incast at any one time, and these also receive their share of normal traffic.) As the incast degree increases, more small flows share physical queues with incast flows, leading to more HoL blocking.

In App. A.1, we further explore this issue with microbenchmarks designed to trigger a variable number of active flows at the bottleneck switch. We show that by adding a very simple end-to-end control mechanism to BFC, we can ameliorate the impact of HoL blocking while still fully utilizing the link.

6.4 Dynamic Queue Assignment

We next consider the effect of applying BFC's dynamic queue assignment separately from the backpressure mechanism. For this, we modified HPCC with idealized re-

transmission (HPCC-PFC) to add stochastic fair queuing (HPCC-PFC+SFQ) and dynamic queue assignment (HPCC-PFC+DQA). To match BFC, we use 32 physical queues with HPCC. We repeat the experiment from Fig. 11a, showing tail slowdown and buffer occupancy for the HPCC variants, BFC, and IdealFQ in Fig. 14.

Adding SFQ to HPCC improves short flow latency by isolating them from long flows in different queues, but it still suffers from more collisions (and thus higher tail latency for short flows) than DQA. DQA on its own, however, has no benefit for long flows: since HPCC is unable to adapt to rapid changes in the number of flows (and the fair-share rate), it is unable to fully utilize the link for long flows, even with DQA. Moreover, both HPCC-PFC+SFQ and HPCC-PFC+DQA build deep buffers and experience drops at the same rate as HPCC-PFC. Notice that HPCC's lower throughput for long flows favors short flows to such an extent that HPCC-PFC+DQA achieves better tail latency for short flows than both BFC and IdealFQ.

6.5 Additional Experiments

In App. A, we use our simulation framework to further characterize the limits of BFC, compare BFC to Homa, as well as study the impact of priority scheduling, parameter selection, locality in the traffic matrix, slow start, incast labelling, and other factors.

7 CONCLUSION

In this paper, we present Backpressure Flow Control (BFC), a practical congestion control architecture for data center networks. BFC provides per-hop per-flow flow control, but with bounded state, constant-time switch operations, and careful use of buffers. Switches dynamically assign flows to physical queues, allowing fair scheduling among competing flows and use selective backpressure to reduce buffering with minimal head of line blocking. Relative to existing end-to-end congestion control schemes, BFC improves short flow tail latency and long flow utilization for networks with high bandwidth links and bursty traffic. We demonstrate BFC's feasibility by implementing it on Tofino2, a state-of-art P4-based programmable hardware switch. In simulation, compared to several deployed end-to-end schemes, BFC achieves $2.3\text{-}60\times$ lower tail latency for short flows and $1.6\text{-}5\times$ better average completion time for long flows.

A ADDITIONAL EXPERIMENTS

In this appendix, we present a more complete set of simulation results for BFC. We first summarize those results, and then present them.

Understanding the Limits of BFC: A limitation of BFC is that performance can degrade when collisions occur. The worst case is when many long-running flows share a bottleneck link with bursty traffic. We synthetically create this scenario and show that by adding a very simple end-to-end control system to BFC, we can largely ameliorate the impact of long flows, while still fully utilizing the link. See App. A.1 for details.

Comparison with Homa: Homa is a receiver driven data center transport that uses network priorities to achieve an approximation of the shortest remaining flow first (SRF) scheduling to provide low latency for short flows while still using the full bandwidth of the bottleneck for long flows. Homa also uses packet spraying. In App. A.2, we configure BFC with a similar scheduling policy. We show that Homa with packet spraying outperforms BFC, but when we turn off packet spraying, BFC outperforms Homa.

Priority Scheduling: Data center operators often classify traffic into multiple classes and use scheduling priorities to ensure performance for the most time-sensitive traffic. We repeat the experiment in Fig. 11b but with traffic split equally among four priority traffic classes, and show that BFC performs well in this case. See App. A.3 for details.

Parameter Sensitivity: We perform parameter sensitivity analysis for HPCC, DCTCP and ExpressPass. See App. A.4 for details.

Spatial Locality: We repeat the experiment in Fig. 11 with spacial locality in source-destination pairs such that the average load on all links across the network is same. The trends in performance are similar. See App. A.5 for details.

Slow-start: We evaluate the impact of using TCP slow-start instead of starting flows at line rate. We repeat the experiment in Fig. 11 and compare the original DCTCP with slow start (DCTCP + SS) and our modified DCTCP where flows start at the line rate. With incast, DCTCP + SS reduces buffer occupancy by reducing the intensity of incast flows, improving tail latency. However, it also increases median FCTs by up to 2×. Flows start at a lower rate, taking longer to ramp up to the desired rate. In the absence of incast, it increases both the tail and median FCT for short flows. See App. A.6 for details.

Reducing Contention for Queues: We tried a variant of BFC where the sender labels incast flows explicitly (similar to the potential optimization in [49]). All the incast flows at an egress port are assigned to the same queue. This frees up queues for non-incast traffic and reduces collisions substantially under large incasts. (see App. A.7).

Incremental Deployment: We repeated the experiment in Fig. 11a in the scenario where (i) BFC is deployed in part of
Figure 15: Median FCT slowdown for mice flows in the presence of long-running flows.

the network; (ii) The switch doesn't have enough capacity to handle all the recirculations. The impact on FCTs is minimal under these scenarios (see App. A.8).

Performance in Asymmetric Topologies: BFC makes no assumption about the topology, link speeds and link delays. We evaluate the performance of BFC in a multi-data-center topology. BFC achieves low FCT for flows within the data center, and high link utilization for the inter-data-center links (see App. A.9).

Dynamic vs. Stochastic Queue Assignment in BFC: We repeat the experiment in Fig. 11a but use stochastic hashing to statically assign flows to physical queue instead. With stochastic assignment, the number of collisions in physical queues increases, hurting FCTs (see App. A.10).

Size of Flow Table: Reducing the size of the flow table can increase index collisions in the flow table, potentially hurting FCTs. We repeat the experiment in Fig. 11a and evaluate the impact of size of flow table. Reducing the size partly impacts the short flow FCTs (see App. A.11).

Incast Flow Performance: App. A.12 shows the slowdown for incast flows for the Google workload used in Fig. 9. BFC reduces the FCT for incast flows compared to other feasible schemes.

A.1 Understanding the limits of BFC

This section investigates the impact of large numbers of active flows on BFC's performance through controlled microbenchmarks. We also show that adding a simple end-to-end flow control mechanism on top of pure BFC helps alleviate the performance impairments caused by large numbers of flows.

Collisions hurt performance in two ways. Consider a congested port X. First, at X, the packets of a short flow can get stuck behind the packets of a long flow sharing the same queue, increasing the FCT. Such performance degradation occurs when the number of active flows exceeds the number of queues at X. Second, X can pause an upstream queue. Unrelated flows sharing this upstream queue will get paused even though they are not going through the congested port X (congestion spreading). BFC can leverage the larger number of upstream queues at the upstream switches to limit congestion spreading (§3.3.1). Typically, congestion spreads only once the number of flows at the congested port exceeds the total number of upstream queues. As a result, in larger topologies with more upstream switches, congestion spreading is harder to create.

To illustrate these issues, we conduct experiments on our standard topology (§6.2.1) where we create different numbers of long-running elephant flows destined to the same receiver (Receiver *A*). All elephant flows start at the beginning of the experiment. We then create two groups of short flows: (1) destined to the same receiver *A* (referred as "direct" mice flows), and (2) destined to a different receiver *B* in the same rack as receiver *A* (referred to as "indirect" mice flows). The aggregate load for each group of mice flows is 3% of the link capacity, and the size of the mice flows is 1 KB. Fig. 15 shows the median FCT slowdown for mice flows as we vary the number of long-running flows. We show results for BFC with 32 and 128 queues, and also IdealFQ (described in §6.2.1) for reference. As expected, for direct mice flows, the FCT degrades when the number of long-running flows exceeds the number of queues. For indirect flows, the degradation only happens when long flows exceed $8\times$ the number of queues, since the topology has 8 spine switches connected to each ToR switch. In this case, some indirect mice flows get paused unnecessarily because they share an upstream queue with a paused long-running flow.

Combining end-to-end congestion control with BFC: In the previous experiment, each long-running flow can build up to 1 Hop-BDP of buffering before getting paused. With *N* long-running flows, in the worst case, a mice flow experiencing a collision can get stuck behind $N\times$ 1-Hop BDP of buffering. BFC can use a simple end-to-end congestion control mechanism to reduce this buffering and limit HoL blocking. This mechanism is helpful in scenarios with persistently large numbers of active flows. As our evaluations showed (§6.3), even in workloads with high load and occasional large-scale incast, pure BFC (with no end-to-end control) performs well except in extreme cases.

Augmenting BFC with end-to-end control is simple. The main goal of the end-to-end control is to prevent flows from sending an excessively large number of packets into the network. Importantly, the end-to-end mechanism need not try to accurately control queuing, react quickly to bursts, or achieve fairness — typical requirements for low-latency data center congestion control protocols — since BFC already achieves these goals.

As an example, we implemented a simple delay-based congestion control that tries to maintain the end-to-end RTT at a certain threshold (RTT_{Target}). We chose a high RTT_{Target} value of $2.5\times$ base RTT to avoid hurting the throughput of long flows, exploiting the fact that it isn't necessary to tightly control queuing in BFC. The algorithm adjusts the sender's window (*w*) as follows.

With the above rule, the window of a sender roughly goes from $w \rightarrow w \times \frac{\text{RTT}_{Target}}{RTT}$ within an RTT. Fig. 15 shows the performance with this variant (BFC 32 (CC)). The performance is close to IdealFQ in all the cases. To check if this change negatively affected the overall behavior of BFC, we repeat the principle experiment in Fig. 11 (Facebook work-

$$\text{RTT}_{Target} = 2.5\times \text{ Base RTT};$$
$$w = 1 \text{ BDP};$$
for *each Acknowledgement* **do**
  if $RTT > RTT_{Target}$ **then**
    $w = w - \frac{\text{RTT} - \text{RTT}_{Target}}{RTT}$
  else
    $w = w + \frac{\text{RTT}_{Target} - RTT}{RTT}$

Algorithm 1: Simple end-to-end congestion control

(a) 55% + 5% 100-1 incast   (b) 60%
Figure 16: 99th percentile FCT slowdown when combined with congestion control. Facebook workload, same setup as Fig. 11.

load) with BFC 32 (CC). Fig. 16 shows the 99th percentile FCT slowdowns. The FCTs of long flows are similar to that of the original BFC (within 10%). However, in the presence of incast, adding congestion control improves the 99th percentile FCT of short flows and the peak buffer occupancy by 30%. While using end-to-end congestion control can improve performance under frequent collisions (and we advocate supplementing BFC with such a mechanism in practice), in this paper we focus on BFC without any such mechanism to better understand the core benefits and limitations of BFC in its purest form.

In App. A.7, we experiment with a variant of BFC where the sender labels incast flows explicitly (similar to the potential optimization in [49]). All the incast flows at an egress port are assigned to the same queue. This frees up queues for non-incast traffic and reduces collisions substantially under large incasts.

A.2 Comparison with Homa

Homa is a receiver driven data center transport that uses network priorities to achieve an approximation of shortest-remaining-flow-first (SRF) scheduling. Homa divides a flow's data into unscheduled (first BDP of traffic) and scheduled categories. The sender assigns a fixed priority level to a flow's unscheduled bytes based on its size and the flow size distribution of the workload. The unscheduled bytes are transmitted at line rate. The receiver assigns priority levels to the scheduled bytes and issues grants (credits) for them. Homa assumes per-packet spraying to ensure load balancing across core links, and sufficient core capacity to guarantee minimal congestion in the core.

While we focus on fair queuing in this paper, BFC's design is applicable to other scheduling policies. In this section, we

(b) Facebook Hadoop, 60%

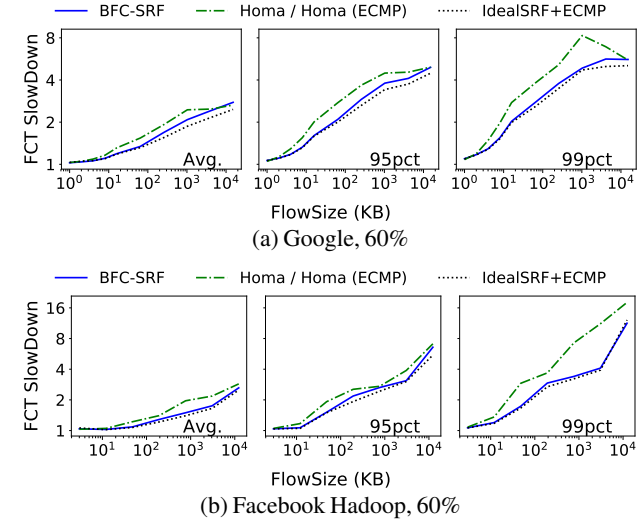
Figure 18: BFC's dynamic queueue assignment achieves a better approximation of the SRF scheduling policy. BFC-SRF achieves close to optimal FCTs.

evaluate a variant of BFC, BFC-SRF, that aims to approximate SRF. Flows insert their remaining size into a header field in each packet transmitted, and the switch schedules queues in order of remaining size of the packet at the head of the queue. Similarly to Homa, NICs also follow SRF scheduling. We ran Homa using its OMNet++simulator [2]. The Homa simulator assumes unbounded buffers at the switch. For BFC, we use a 12 MB shared buffer. We use 32 queues for both Homa and BFC. For Homa, the 32 priority levels are divided between unscheduled and scheduled priorities based on the ratio of unscheduled and scheduled traffic; the overcommitment level is equal to the number of scheduled priorities [49]. We use our default topology with 128 servers and 2:1 oversubscription at the ToR uplinks (§6.2.1).

Two differences between Homa and BFC-SRF are worth highlighting. First, BFC-SRF uses flow-level ECMP rather than packet spraying for enforcing per-flow backpressure. Second, BFC-SRF uses dynamic queue assignment and performs SRF scheduling directly on the switch, as opposed to Homa's priority assignment from the end-points. To understand the impact of these aspects separately, we also evaluate a variant of Homa with ECMP, and report results for IdealSRF+ECMP, an idealized SRF scheme with unlimited queues and unbounded buffers at each switch with ECMP load balancing.

We repeat the experiments in Fig. 10 and Fig. 11b for the Google and Facebook workloads at 60% load (log-normal flow arrivals without incast). Fig. 17 reports the FCTs. Homa performs the best out of all schemes, achieving up to 2$\times$ better FCTs for long flows. With packet spraying, flows encounter minimal congestion in the core, and compete for bandwidth primarily at the last-hop. In contrast, ECMP is prone to path collisions [7] and flows encounter congestion in the core. Notice that a last-hop link carries half the load of a core


link (30% vs 60%) in this experiment on average (§6.2.1). Since packet spraying essentially eliminates congestion on the core links, with Homa flows experience congestion only on the last-hop links. But with the ECMP-based schemes, flows contend at the core links (with 2$\times$ the load). As a result, Homa even outperforms IdealSRF+ECMP. This result illustrates the benefits of packet spraying; nevertheless, packet spraying is rarely deployed in practice because it can cause packet reordering, increasing CPU overhead at endpoints[7], and it can hurt performance in asymmetric topologies (e.g., caused by rolling upgrades or link failures) [60].

Among the ECMP approaches, BFC-SRF is close to IdealSRF+ECMP and Homa is worse. In Homa, receivers have no visibility into congestion in the core and don't react to queue buildup in the core (though each flow limits its total in-flight data to 1 BDP). Also, Homa's receiver-set priorities are only based on contending flows at the last hop, and can violate SRF scheduling when congestion occurs in the core. Table 2 shows that with ECMP, the scheduled traffic encounters significantly higher queuing in the core.

Benefits of BFC's dynamic queue assignment over Homa. BFC makes queue assignment and scheduling decisions at the switch, based on an instantaneous view of competing flows. In principle, this should allow BFC to more accurately approximate SRF compared to Homa. To understand if this

(b) Facebook Hadoop, 55% + 5% 100-1 incast

Figure 19: FCT slowdown with 100-1 incast. Collisions in BFC-SRF can cause priority inversions hurting FCTs

is actually the case, we conduct an experiment with the same Google and Facebook workloads but with all flows destined to a single receiver, and the senders located within the same rack as the receiver. Since there is no traffic in the core, load balancing (ECMP vs. packet spraying) does not matter in this case. Flow arrivals are log-normal and the load on the receiver's link is 60%. Fig. 18 shows the results. BFC-SRF achieves better FCTs primarily at the tail.

We give two examples of priority inversions in Homa which BFC avoids. First, the Homa sender assigns priorities to unscheduled traffic based on flow size distributions rather than using the current set of flows competing at the switch due to lack of visibility for the first RTT. As a result with Homa, short flows (< 1 BDP) with similar flow sizes can end up sharing unscheduled priority queues unnecessarily, even when there are sufficient queues at the switch to assign each flow a unique queue. Second, in Homa the unscheduled bytes of a flow are always scheduled ahead of the scheduled bytes of competing flows. This implies that the unscheduled bytes of a new long flow will be *incorrectly* scheduled ahead of the scheduled bytes of a shorter flow. This also violates SRF and increases FCT for flows larger than a BDP.

Impact of collisions on BFC-SRF. Recall that with large incast, BFC can experience collisions. For BFC-SRF, such collisions can cause priority inversions that hurt FCTs. To illustrate this, we repeat the experiments in Fig. 9 and Fig. 11a (55% load plus 5% 100-1 incast traffic). Fig. 19 shows that the average FCT for short flows is higher with BFC-SRF. This is because of high completion times for a (small) fraction of short flows sharing queues with longer flows. To understand why, consider the following situation. An incoming short flow arrives when there are no free queues, and ends up sharing the queue with a long flow. Let's say the remaining size of the long flow is greater than the incast flow size (200 KB in

this experiment). In case there are competing incast flows present in other queues, the incast flows will be scheduled ahead of this long flow. Therefore, the short flow will have to wait for *all* the traffic from the incast flows to finish to make any progress. This can severely degrade its completion time. The core of this problem is that when a port runs out of queues, the BFC switch assigns the new flow to a queue randomly. This is fine for fair queuing but with SRF, a more sophisticated strategy may improve performance (e.g., assign the new flow to a queue with similar remaining flow sizes).

As explained earlier, Homa is not immune to priority inversions. Fig. 19 shows that with Homa, flows with size greater than 1 BDP but less than 2 BDP have high FCTs at the tail. This is because unscheduled bytes of the the incast flows are incorrectly scheduled ahead of the scheduled bytes of such flows.

These experiments suggest an interesting possibility to try to get the best of both schemes: we could combine BFC's dynamic queue assignment for unscheduled traffic with Homa's grant mechanism for controlling scheduled traffic. We leave exploration of such a design to future work.

A.3 Multiple traffic classes

Many data center operators allocate network traffic into a small number of priority traffic classes to ensure that mission critical traffic is delivered with low tail latency, while other traffic is delivered according to its quality of service needs. BFC has a simple extension to support priority groups. To avoid priority inversion where a flow at one priority can be stalled behind a flow of a lower priority, we assume queues at a port are statically assigned to different priority levels. The switch performs dynamic queue assignment for each class independently. A flow with priority X is only assigned to physical queues associated with that priority. Queues at the same priority level follow fair scheduling.

Statically partitioning physical queues among traffic classes could make it more likely for traffic within a class to run out of queues and suffer degraded performance with collisions and HoL blocking. On the other hand, high priority traffic is preferentially scheduled, leading to short queues and few active flows. Collisions will be more likely at lower priority traffic classes, where performance is already degraded. Priority scheduling results in rapid and extreme changes in the available rate for these background classes. Relative to end-to-end control, per-hop backpressure can more easily utilize rapidly changing spare capacity.

To test how BFC behaves with multiple traffic classes, we repeat the experiment in Fig. 11b: Facebook workload, 60% load, and no incast. We configure the system with 4 priority classes, each with equal load (15% each, 60% in aggregate). We allocate physical queues evenly to each traffic class. We consider configurations with 32 and 128 queues per port (8 or 32 queues per class). We also show results for HPCC and DCTCP. In this study, DCTCP marks packets based on per-
(a) Priority Class 1 (highest)   (b) Priority Class 2   (c) Priority Class 3   (d) Priority Class 4 (lowest)

Figure 20: Multiple traffic classes with BFC, reporting 99th percentile FCT slowdown for the Facebook workload, 60% load, and no incast.

class queueing, while HPCC uses switch aggregates. Fig. 20 shows the 99th percentile FCT slowdown for different priority classes. BFC achieves good performance across all traffic classes and flow sizes. In particular, BFC achieves up to $5\times$ better tail latency for short flows than DCTCP. At the lowest priority level, DCTCP's short flow tail latency converges to that of BFC. For low priority flows, tail latency is primarily governed by time spent waiting to be scheduled at the switch.

HPCC's performance is somewhat anomalous. Long flows suffer priority inversion, where long flows at high priority achieve significantly worse service than short flows at lower priority. In HPCC, long flows back off in an attempt to keep queues empty. The (transient) extra capacity left by such long flows can be used by short flows traffic at all priority levels, improving performance for these short flows.

BFC has only slightly better performance with 32 vs. 8 queues per priority level, indicating that collisions did not have much impact. For high priority traffic, the setup is equivalent to running our experiment with just one traffic class at 15% load and a small number of queues—even modest numbers of active queues are unlikely at such low load. Lower priority traffic can run out of queues, but they gain the benefit of being able to take immediate advantage when the high priority queues are empty. In other words, work conserving behavior is more important for background traffic than the number of queues. We acknowledge this is just one study, and there are likely scenarios where BFC's performance could suffer when using multiple traffic classes.

One obvious improvement is to split queues dynamically among classes rather than statically. But in the long run, we strongly believe that the number of queues per port is likely to continue to grow to whatever is needed to deliver good performance.

A.4 Parameter sensitivity for comparison schemes

In this section, we perform sensitivity analysis to understand the impact of parameters on performance of HPCC, DCTCP and ExpressPass. We repeat the experiment in Fig. 11b (Facebook distribution with 60% load). Fig. 21 reports the average, 95th and 99th percentile flow completion times as we vary the parameters. In general, we observe that parameters present a trade-off between the latency of short flows (queuing) and the throughput of long flows (link utilization).

HPCC: We vary the target utilization (η) from 90 to 98%.

(a) HPCC (η)

(b) DCTCP (ECN marking threshold: K_{min}-K_{max})

(c) ExpressPass (Credit Buffer Size)
(d) ExpressPass (α)

Figure 21: 99th percentile FCT slowdown for the Facebook workload, 60% load without incast. Sensitivity to the choice of parameters in HPCC, DCTCP, and ExpressPass.

As expected, increasing η worsens the FCT of short flows but improves the FCT for long flows (marginally for both), see Fig. 21a.

DCTCP: We vary the ECN marking threshold governed by parameters K_{min} and K_{max}. Increasing the threshold increases the queuing at the switch, which increases FCT of short flows but improves link utilization (Fig. 21b).

(d) 60%
(Median FCT)

Figure 23: Impact of using slow start on median and 99th percentile tail latency FCT slowdown, for the Facebook flow size distribution with and without incast (setup the same as Fig. 11). With incast, DCTCP + SS (slow start) reduces the tail FCT, but it increases median FCTs by up to 2 ×. In the absence of incast, DCTCP + SS increases both the tail and median FCT for short and medium flows.

ExpressPass: Varying the credit buffer size has little impact on performance (Fig. 21c). We vary α, which controls how the receiver credits are generated. Reducing α reduces "credit waste", improving the FCT of long flows. However, it also increases the FCT of short flows (Fig. 21d).

A.5   Impact of Spatial Locality

We repeated the experiment from Fig. 11 with spatial locality in source-destination pairs such that the average load on all links across the network is same. Fig. 22 shows the 99th percentile slowdowns. The trends are similar to Fig. 11.

A.6   Using TCP Slow-start

We also evaluate the impact of using TCP slow-start instead of starting flows at line rate in Figure 23. We compare the original DCTCP with slow start (DCTCP + SS) with an initial window of 10 packets versus the modified DCTCP used so far (initial window of the BDP). The setup is same as Fig. 11.

With incast, DCTCP + SS reduces buffer occupancy by reducing the intensity of incast flows, improving tail latency (Fig. 23a). However, slow start increases the median FCT substantially (Fig. 23c). Flows start at a lower rate, taking

(a) Average FCT for long flows   (b) Tail FCT for short flows
Figure 24: FCT slowdown for short and long flows as a function of incast degree. The x axis is not to scale. By isolating incast flows, BFC + IncastLabel reduces collisions and achieves the best performance.

longer to ramp up to the desired rate. For applications with serially dependent flows, an increase in median FCTs can impact the performance substantially.

In the absence of incast, slow start increases both the tail (Fig. 23b) and median (Fig. 23d) FCT for the majority of flow sizes. In particular, short flows are still slower than with BFC, as slow start does not remove burstiness in buffer occupancy in the tail.

A.7   Reducing contention for queues

To reduce contention for queues under incast, we tried a variant of BFC where the sender labels incast flows explicitly (similar to the potential optimization in [49]). BFC + IncastLabel assigns all the incast flows at an egress port to the same queue. This frees up queues for non-incast traffic, reducing collisions and allowing the scheduler to share the link between incast and non-incast traffic more fairly.

Fig. 24 shows the performance of BFC + IncastLabel in the same setup as Fig. 13. The original BFC is shown as BFC + Flow FQ for per-flow fair queuing. BFC + IncastLabel achieves the best performance across all the scenarios. However, the FCTs for incast flows is higher compared to BFC + Flow FQ (numbers not shown here). When there are multiple incast flows at an ingress port, the incast flows are allocated less bandwidth in aggregate compared to per-flow fair queuing.

While BFC + IncastLabel achieves great performance, it assumes the application is able to label incast flows, and so we use a more conservative design for the main body of our evaluation.

A.8   Incremental Deployment

We repeated the experiment in Fig. 11a in the scenario where i) BFC is deployed in part of the network; ii) The switch doesn't have enough capacity to handle all the recirculations. Fig. 25 reports the tail FCT and buffer occupancy for these settings.

Partial deployment in the network: We first evaluate the situation when BFC is only deployed at the switches and the sender NICs don't respond to backpressure signal (shown as BFC - NIC). To prevent sender NIC traffic from filling up the buffers at the ToR, we assume a simple end-to-end congestion control strategy where the sender NIC caps the in-flight packets for a flow to 1 end-to-end bandwidth
(a) 99th percentile FCT   (b) Buffer Occupancy

Figure 25: FCT slowdown (99th percentile) and buffer occupancy distribution for two BFC variants. When NICs don't respond to backpressure (BFC - NIC), BFC experiences moderate increased buffering. Using sampling to reduce recirculation (BFC + sampling) has marginal impact on performance.

delay product (BDP). As expected, BFC - NIC experiences increased buffering at the ToR (Fig. 25b). However, the tail buffer occupancy is still below the buffer size and there are no drops. Since all the switches are BFC enabled and following dynamic queue assignment, the frequency of collisions and hence the FCTs are similar to the orignal BFC.

Sampling packets to reduce recirculations: A BFC switch with an RMT architecture [18] recirculates packets to execute the dequeue operations at the ingress port. Depending on the packet size distribution of the workload, a switch might not have enough packet processing (pps) capacity or recirculation bandwidth to process these recirculated packets. In such scenarios, we can reduce recirculations by sampling packets. Sampling works as follows.

On a packet arrival (enqueue), sample to decide whether a packet should be recirculated or not. Only increment the pause counter and `size` in the flow table for packets that should be recirculated. The dequeue operations remain as is and are only executed on the recirculated packets. The `size` now counts the packets sampled for recirculation and residing in the switch. While sampling reduces recirculations, it can cause packet re-ordering. Recall, BFC uses `size` to decide when to reassign a queue. With sampling, `size` can be zero even when a flow has packets in the switch. This means a flow's queue assignment can change when it already has packets in the switch, causing reordering. However, sticky queue assignment should reduce the frequency of these events (§3.3.2).

We now evaluate the impact of sampling on the performance of BFC (shown as BFC + Sampling). In the experiment, the sampling frequency is set to 50%, i.e., only 50% of the packets are recirculated. BFC + Sampling achieves nearly identical tail latency FCT slowdowns and switch buffer occupancy as the orignal BFC. With sampling, fewer than 0.04% of the packets were retransmitted due to packet reordering.

A.9 Cross data center traffic

For fault tolerance, many data center applications replicate their data to nearby data centers (e.g., to a nearby metro area). We evaluate the impact of BFC on managing cross-data center congestion in such scenarios. We consider the ability

(a) 99th percentile FCT   (b) Utilization at the interconnect.
Figure 26: Performance in cross data center environment where two data center are connected by a 200 μs link, for the Facebook workload (60% load) with no incast traffic. The left figure shows the 99th percentile FCT slowdown for intra-data-center flows. The right figure shows the average utilization of the link connecting the two data centers.

of different systems to achieve good throughput for the inter-data-center traffic, and we also consider the impact of the cross-data-center traffic on tail latency of local traffic, as the larger bandwidth-delay product means more data is in-flight when it arrives at the bottleneck.

We created a Clos topology with 64 leaf servers, and 100 Gbps links and 12 MB switch buffers. Two gateway switches connect the data centers using a 200 Gbps link with 200 μs of one-way delay (i.e. the base round trip delay of the link is 400 μs), or roughly equivalent to the two data centers being separated by 50 km assuming a direct connection. The experiment consists of intra-data-center flows derived from the Facebook distribution (60% load). Additionally, there are 20 long-lived inter-data-center flows in both the directions.

Fig. 26a shows the 99th percentile tail latency in FCT slowdown for intra-data-center flows for BFC, HPCC and DCQCN.[8] Fig. 26b shows the average utilization of the link connecting the two data centers (interconnect), a proxy for the aggregate throughput of the long-lived inter-data-center flows. BFC is better for both types of flows. With BFC, the link utilization of the wide area interconnect is close to 100%, while neither HPCC nor DCQCN can maintain the link at full utilization, even with ample parallelism. This is likely a consequence of slow end-to-end reaction of the inter-data-center flows [52]. The congestion state on the links within a data center is changing rapidly because of the shorter intra-data-center flows. By the time an inter-data-center flow receives congestion feedback and adjusts its rate, the congestion state in the network might have already changed. When capacity becomes available, the inter-data-center flows can fail to ramp up quickly enough, hurting its throughput.

Relative to the single data center case (cf. Fig. 11b), tail latency FCTs are worse for all three protocols, but the relative advantage of BFC is maintained. Where HPCC has better tail latency than DCQCN in the single data center case for both short and medium-sized flows, once inter-data-center traffic is added, HPCC becomes worse than DCQCN. With bursty workloads, on the onset of congestion, the long-lived

---

[8]Data center operators have developed specialized protocols for better inter-data center link management [21]; comparing those to BFC is future work.

(a) 99th percentile FCT   (b) Collisions

Figure 27: Performance of BFC with stochastic queue assignment, for the workload in Fig. 11a. BFC + Stochastic incurs more queue collisions leading to worse tail latency especially for small flows compared to BFC + Dynamic.

flow will take an end-to-end RTT to reduce its rate, and can build up to 1 BDP (or 500 KB) of buffering, hurting the tail latency of intra-data-center traffic. This has less of an impact on DCQCN because it utilizes less of the inter-data-center bandwidth in the first place.

In contrast, BFC reacts at the scale of the hop-by-hop RTT. Even though inter-data-center flows have higher end-to-end RTTs, on switches within the data center, BFC will pause/resume flows on a hop-by-hop RTT timescale ($2\,\mu$s). As a result, with BFC, tail latencies of intra-data-center flows are relatively unaffected by the presence of inter-data-center flows, while the opposite is true of HPCC.

A.10   Physical queue assignment

To understand the importance of dynamically assigning flows to physical queues, we repeated the experiment in Fig. 11a with a variant of BFC, BFC + Stochastic, where we use stochastic hashing to statically assign flows to physical queues (as in SFQ). In BFC (referred as BFC + Dynamic here), the physical queue assignment is dynamic. To isolate the effect of changing the physical queue assignment, the pause thresholds are the same as BFC + Dynamic.

Fig. 27a shows the tail latency. Compared to BFC, tail latency for BFC + Stochastic is much worse for all flow sizes. Without the dynamic queue assignment, flows are often hashed to the same physical queue, triggering HoL blocking and hurting tail latency, even when there are unoccupied physical queues. Fig. 27b is the CDF of such collisions. BFC+Stochastic experiences collisions in a high fraction of cases and flows end up being paused unnecessarily. Such flows finish later, further increasing the number of active flows and collisions. Even with incast, the number of active flows in BFC is smaller than the number of physical queues most of the time.

A.11   Size of flow table

We repeated the experiment in Fig. 11a, but varied the size of the flow table (as a function of the number of queues in the switch). The default in the rest of the paper uses a flow table of 100X. Fig. 28 shows the tail latency as a function of flow size, for both smaller and larger flow tables. Reducing the size of the flow table increases the index collisions in the flow

(a) 99th percentile FCT
Figure 28: FCT slowdown (99th percentile) for BFC for different size flows as a function of the size of the flow table (as a multiple of the number of queues in the switch). The other experiments in the paper use a flow table of 100X. Further reducing the size of the flow table hurts small flow performance.
Figure 29: FCT slowdown for incast traffic. Slowdown is defined per flow. BFC reduces the FCT for incast flows compared to other feasible schemes. Setup from Fig. 9.

table. Each flow table collision means that those flows are necessarily assigned to the same physical queue. Tail latency FCTs degrade as a result, particularly for small flows and for smaller table sizes. This experiment shows that increasing the size of the flow table would moderately improve short flow tail latency for BFC.

A.12   Incast flow performance

Fig. 29 shows the slowdown for incast flows for the Google workload used in Fig. 9. The benefits of BFC for non-incast traffic do not come at the expense of worse incast performance. Indeed, BFC improves the performance of incast flows relative to end-to-end congestion control, because it reacts faster when capacity becomes available at the bottleneck, reducing the percentage of time the bottleneck is unused while the incast is active.

B   DEADLOCK PREVENTION

We formally prove that BFC is deadlock-free in absence of cyclic buffer dependency. Inspired by Tagger [32], we define a backpressure graph ($G(V,E)$) as follows:

1. Node in the graph (V): A node is an egress port in a switch and can thus be represented by the pair <switchID, egressPort>.
2. Edge in the graph (E): There is a directed edge from $B \rightarrow A$, if a packet can go from A to B in a single hop (i.e., without traversing any other nodes) and trigger backpressure from $B \rightarrow A$. Edges represent how backpressure can propagate in the topology.

We define deadlock as a situation when a node (egress port) contains a queue that has been paused indefinitely.

Cyclic buffer dependency is formally defined as the situation when G contains a cycle.

Theorem 1 *BFC is deadlock-free if $G(V,E)$ does not contain any cycles.*

Proof: We prove the theorem by using contradiction.

Consider a node A that is deadlocked. A must contain a queue (A_q) that has been indefinitely paused as a result of backpressure from the downstream switch. If all the packets sent by A_q were drained from the downstream switch, then A_q will get unpaused (§3.3.2). There must be at least one node (B) in the downstream switch that triggered backpressure to A_q but hasn't been able to drain packets from A_q, i.e., B is deadlocked. This implies, in G, there must be an edge from $B \rightarrow A$. Applying induction, for B there must exist another node C (at the downstream switch of B) that is also deadlocked (again there must be an edge from $C \rightarrow B$). Therefore, there will be an infinite chain of nodes which are paused indefinitely, the nodes of the chain must form a path in G. Since G doesn't have any cycles, the paths in G can only be of finite length, and therefore, the chain cannot be infinitely long. A contradiction, hence proved.

Preventing deadlocks: To prevent deadlocks, given a topology, we calculate the backpressure graph, and pre-compute the edges that should be removed so that the backpressure graph doesn't contain any cycles. Removing these edges thus guarantees that there will be no deadlocks even under link failures or routing errors. To identify the set of edges that should be removed we can leverage existing work [32].

To remove a backpressure edge $B \rightarrow A$, we use the simple strategy of skipping the backpressure operation for packets coming from A going to B at the switch corresponding to B.[9] Note that, a switch can identify such packets *locally* using the ingress and egress port of the packet. This information can be stored as a match-action-table (indexed by the ingress and egress port) to check whether we should execute the backpressure operations for the packet.

For Clos topologies, this just includes backpressure edges corresponding to packets that are coming from a higher layer and going back to a higher layer (this can happen due to rerouting in case of link failures). Note that, usually the fraction of such packets is small ($< 0.002\%$ [32]), so forgoing backpressure for a small fraction of such packets should hurt performance marginally (if at all).

C   IMPACT OF PAUSE THRESHOLD

A consequence of the simplicity of BFC's backpressure mechanism is that a flow can temporarily run out of packets

---

[9]To remove backpressure edges in PFC, Tagger uses a more complex approach that invloves creating new cycle free backpressure edges corresponding to the backpressure edges that should be removed. To ensure losslessness, Tagger generates backpressure using these new cycle free edges instead of the original backpressure edge. In our proposed solution, we forgo such requirement for simplicity.

at a bottleneck switch while the flow still has packets to send. The pause threshold (Th) governs the frequency of such events. Using a simple model, we quantify the impact of Th.

Consider a long flow f bottlenecked at a switch S. To isolate the impact of the delay in resuming, we assume that f is not sharing a queue with other flows at S or the upstream switch. Let μ_f be the dequeue rate of f at S, i.e., when f has packets in S, the packets are drained at a steady rate of μ_f. Similarly, let $\mu_f \cdot x$ be the enqueue rate of f at the switch, i.e., if f is not paused at the upstream, S receives packets from f at a steady rate of $\mu_f \cdot x$. Here, x denotes the ratio of enqueue to dequeue rate at S. Since f is bottlenecked at S, $x > 1$.

We now derive the fraction of time in steady state that f will not have packets in S. We show that this fraction depends only on x and Th, and is thereby referred as $E_f(x,Th)$.

The queue occupancy for f will be cyclic with three phases.
- Phase 1: S is receiving packets from f and the queue occupancy in increasing.
- Phase 2: S is *not* receiving packets from f and the queue is draining.
- Phase 3: S is not receiving packets from f while the queue is empty.

The time period for phase 1 (t_{p1}) can be calculated as follows. The queue occupancy at start of the phase is 0 and S is receiving packets from f. f gets paused when the queue occupancy exceeds Th. The queue builds at the rate $\mu_f \cdot x - \mu_f$ (enqueue rate - dequeue rate). The pause is triggered after $\frac{Th}{\mu_f \cdot (x-1)}$ time from the start of the phase. Since the pause takes an $HRTT$ to take effect, the queue grows for an additional $HRTT$. t_{p1} is therefore given by:

$$t_{p1} = \frac{Th}{\mu_f \cdot (x-1)} + HRTT. \quad (1)$$

The queue occupancy at the end of phase 1 is $Th + HRTT \cdot \mu_f \cdot (x-1)$. The time period for phase 2 (t_{p2}) corresponds to the time to drain the queue. t_{p2} is given by:

$$t_{p2} = \frac{Th + HRTT \cdot \mu_f \cdot (x-1)}{\mu_f}. \quad (2)$$

At the end of phase 2, there are no packets from f in S. As a result, S resumes f at the upstream. Since the resume takes an $HRTT$ to take effect, the queue is empty for an $HRTT$. Time period for phase 3 (t_{p3}) is given by:

$$t_{p3} = HRTT \quad (3)$$

Combining the equations, $E_f(x,Th)$ is given by:

$$E_f(x,Th) = \frac{t_{p3}}{t_{p1} + t_{p2} + t_{p3}}$$
$$= \frac{x-1}{\frac{Th}{HRTT \cdot \mu_f} \cdot x + (x^2-1)}. \quad (4)$$
Figure 30: Impact of pause threshold (Th) on the metric of worst case inefficiency. Increasing Th reduces the maximum value for the fraction of time f can run out of packets at the bottleneck.

Notice that for a given x, $E_f(x,Th)$ reduces as we increase Th. Increasing Th, increases the time period for phase 1 and phase 2, and the fraction of time f runs out of packets reduces as a result.

We now quantify the impact of pause threshold on the worst case (maximum) value of $E_f(x, Th)$. Given a Th, $E_f(x,Th)$ varies with x. When $x \to 1$, $(E_f(x,Th) \to 0)$, and when $x \to \infty$, $(E_f(x,Th) \to 0)$. The maxima occurs somewhere in between. More concretely, for a given value of Th, the maxima occurs at $x = \sqrt{\frac{Th}{HRTT \cdot \mu_f}} + 1$. The maximum value $(\max_{x>1}(E_f(x,Th)))$ is given by:

$$\max_{x>1}(E_f(x,Th)) = \frac{1}{\left(\sqrt{\frac{Th}{HRTT \cdot \mu_f}} + 1\right)^2 + 1}. \qquad (5)$$

Fig. 30 shows how $\max_{x>1}(E_f(x,Th))$ changes as we increase the pause threshold. As expected, increasing the pause threshold reduces $\max_{x>1}(E_f(x,Th))$. However, increasing the pause threshold has diminishing returns. Additionally, increasing Th increases the buffering for f (linearly).

In BFC, we set Th to 1-Hop BDP at the queue drain rate, i.e., $Th = HRTT \cdot \mu_f$. Thereoofore, the maximum value of $E_f(x, Th)$ is 0.2 (at $x = 2$). This implies, under our assumptions, that a flow runs out of packets at most 20% of the time due to the delay in resuming a flow.

Note that 20% is the maximum value for $E_f(x,Th)$. When $x \neq 2$, $E_f(x,Th)$ is lower. For example, when $x = 1.1$ (i.e., the enqueue rate is 10% higher than the dequeue rate), $E_f(x,Th)$ is only 7.6%.

The above analysis suggests that the worst-case under-utilization caused by delay in resuming is 20%. Note that in practice, when an egress port is congested, there are typically multiple flows concurrently active at that egress. In such scenarios, the under-utilization is much less than this worst-case bound, because it is unlikely that all flows run out of packets at the same time. As our evaluation shows, with BFC, flows achieve close to ideal throughput in realistic traffic scenarios (§6).

Packet Order Matters!
Improving Application Performance by Deliberately Delaying Packets

Abstract

Data centers increasingly deploy commodity servers with high-speed network interfaces to enable low-latency communication. However, achieving low latency at high data rates crucially depends on how the incoming traffic interacts with the system's caches. When packets that need to be processed in the same way are consecutive, i.e., exhibit high temporal and spatial locality, caches deliver great benefits.

In this paper, we systematically study the impact of temporal and spatial traffic locality on the performance of commodity servers equipped with high-speed network interfaces. Our results show that (*i*) the performance of a variety of widely deployed applications degrades substantially with even the slightest lack of traffic locality, and (*ii*) a traffic trace from our organization reveals poor traffic locality as networking protocols, drivers, and the underlying switching/routing fabric spread packets out in time (reducing locality). To address these issues, we built Reframer, a software solution that deliberately delays packets and reorders them to increase traffic locality. Despite introducing μs-scale delays of some packets, we show that Reframer increases the throughput of a network service chain by up to 84% and reduces the flow completion time of a web server by 11% while improving its throughput by 20%.

1 Introduction

Recent advances in networking hardware have boosted the speed of Network Interface Cards (NICs) and packet switching devices, facilitating faster Internet access [1, 2] and improving performance in datacenters [3]. At the same time, this sudden growth in networking speeds has not been followed by a similar trend in Central Processing Unit (CPU) core frequencies and memory access latencies [4, 5]. This places tremendous pressure on today's commodity server architectures. Accessing main memory for each packet is prohibitive, thus high-speed packet processing inherently requires packets *and* the instructions & data needed to

process these packets to reside in cache memories to the greatest extent possible. For these reasons, recent efforts have explored ways to optimize cache utilization, for instance, (*i*) using Direct-Memory Access (DMA) or Remote DMA (RDMA) [6] to eliminating CPU involvement in the reception of incoming packets, (*ii*) with Data Direct I/O (DDIO) [7, 8] completely avoiding main memory, (*iii*) placing incoming packets into a Last Level Cache (LLC) slice as close as possible to the core responsible for handling these packets [9], and (*iv*) realizing Network Function (NF) chains *without* inter-core communication (thus eliminating LLC cache pollution) [10] and *with* whole-stack optimizations (minimizing LLC accesses) [11].

Optimal utilization of memory caches requires that packets to be processed (with a given set of instructions *and* data) arrive as close as possible in time to each other, i.e., high *temporal* and *spatial* locality of the received packet stream. In this paper, we investigate the impact of packet ordering on the performance of I/O-intensive applications. We first measure a variety of performance metrics including throughput, average processing cycles per packet, average CPU instructions per packet, etc., as functions of the level of traffic locality of a set of streams of packets . In our experiments, the relevant data is both packets belonging to *the same flow* and the metadata that is associated with them. Our investigation reveals an unexpected sharp performance degradation (up to a factor of 3×) with even the slightest lack of temporal and spatial traffic locality for packets that could have been processed using the same instructions and data. As an example, we discovered that the number of CPU cycles per packet for an iperf server were reduced by a factor of 2−3× when packets arrive in small bursts of 5 packets belonging to the same flow as opposed to bursts of a single packet.

In practice, there are several hindrances to cache-optimized I/O processing. First, slow NICs at the client do not produce bursts of packets that will arrive "back-to-back" at a receiver with a faster NIC. Moreover, the multiplexing of different traffic flows along the path from a client to a server results in packets belonging to a client's flow being spaced apart

(i.e., interleaved with other flows), thus diminishing locality. Even worse, we observe the existence of an increasing *friction* between emerging networking trends, which advocate that congestion control mechanisms pace packets, i.e., spread packets in a flow apart from each other as much as possible to minimize the risk of congestion in the network (see §3), and the desire to process incoming packets in memory caches to the greatest extent possible (due to trends in computer architecture) [12]. To understand whether real-world traffic exhibits sufficient ordering, we analyzed a real-world traffic trace from one of the packet gateway interfaces of our organization. This traffic exhibits a very low level of spatial locality, as more than ~60% of the packets belonging to the same flow are interleaved with packets belonging to other flows, which is far from ideal conditions for cache-optimized packet processing.

These apparently completely opposite requirements of (*i*) pacing traffic for better network-level statistical multiplexing and (*ii*) processing packets in bursts for better cache effectiveness calls for a solution that satisfies both requirements at the same time. Based on the above, we explore the counter-intuitive idea of *increasing packet processing throughput by deliberately delaying and reordering packets before they reach the application running on the server(s)*, thus rebuilding high traffic locality. We built Reframer, a network function that leverages this idea, to buffer and reorder packets between different flows. By introducing Reframer at the *destination* network (or directly at an end server), we (*i*) maximize the number of subsequent cache hits in the servers, thus reducing the processing time for each burst and (*ii*) are compatible with the emerging pacing-based congestion control mechanisms (e.g., BBR [13]) as we do not affect the pacing of the packets across the Internet. Reframer can be deployed on the same server where one needs to increase cache hit performance (e.g., CPU core and/or SmartNIC) or upfront as part of a network function service chain to improve the throughput of the service chain itself by up to 60% (see §5.2) and subsequent web servers throughput by 20% while reducing the flow completion time by 11%, despite delaying the individual packets. Moreover, we show that Reframer improve performance an order of magnitude more than flow-oblivious batching [14], showing the need to increase *per-flow* spatial locality.

Contributions. In this paper, we:

- Unveil that trends in networking, spreading packets apart, are antithetical to today's high-performance computer architectures, which require bursty communication to efficiently use cache memories for high-speed networking.
- Systematically measured the performance degradation due to the lack of spatial locality in the streams of packets processed by servers for a variety of I/O-intensive applications (including large data transfers and network functions). Our results show significant performance degradation, up to a

factor of $2-3\times$, mainly due to cache misses (§2).
- Analyzed the levels of spatial and temporal locality in real-world traffic captured between our organization and our ISP. This traffic shows poor locality, which leads to sub-optimal performance at each of the servers (§3).
- Built a Reframer prototype to reorder packets, thus exploit servers' caches when processing packets at high speed (§4). Reframer improves the throughput and latency of chained NFs by up to 84% and 46% respectively, using a realistic packet trace and various Reframer deployments (§5).

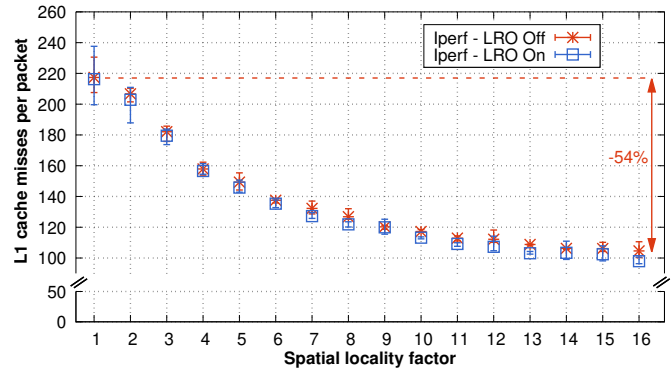
2   How Much Does Order Matter?

This section shows how explicit packet ordering increases temporal and spatial locality and, consequently, boosts the performance of real-world applications. Our results show that, when packets belonging to the same flow are interleaved by even a few other packets, the latency of a packet processing application may increase by more than $2\times$ because of a higher number of cache misses and executed CPU instructions. These results motivate our Reframer system, whose goal is to build *per-flow* batches of packets that can be submitted to the servers, as opposed to batches of *arbitrary* packets belonging to *different flows* as in state-of-the-art software switches (e.g., Batchy [14]).

The experimental methodology used in this section is described in §2.1. We decompose the effects of packet ordering into three categories: network stack effects (§2.2), software switching effects(§2.3), and more advanced NF effects (§2.4).

2.1   Experimental Setup

Testbed. All the experiments in this section use the same testbed. Two back-to-back interconnected servers, each with a single-socket 8-core Intel® Xeon® Gold 5217 (Cascade Lake) CPU clocked at 2.3 GHz and 48 GB of DDR4 RAM at 2666 MHz. Each core has 2×32 KiB L1 (instruction & data caches) and 1 MiB L2 caches, while one 11 MiB LLC is shared among the cores. Each server has a dual port 100 GbE Mellanox ConnectX-5 NIC with firmware version 16.28.1002. Hyper-threading is enabled on both servers and the Operating System (OS) is the Ubuntu 18.04 distribution with Linux kernel v5.3. One server acts as a traffic generator and receiver while the other server is the Device Under Test (DUT). We also utilized the Linux `perf` tool on the DUT during the execution of the experiments to monitor CPU performance counters (e.g., CPU cache misses).

Spatial locality factor (*SLF*). We define *SLF* as the average number of packets, in the same flow, that arrive back-to-back at the DUT. For example, if there are three flows (A, B, and C) and $SLF = 1$, the DUT receives packets in the pattern "ABCABC...". For $SLF = 2$, the pattern is "AABBCC...".
(a) CPU cycles per packet.


(b) L1 cache misses per packet.

Figure 1: Impact of packet spatial locality on the performance of an `iperf` server, with and without LRO.

2.2 Network Stack Effects

Packet ordering has a profound impact on the performance of general purpose network stacks and their applications, especially TCP receive-side processing. In these experiments, we show that lack of traffic locality greatly degrades CPU utilization (up to a factor of $3\times$) even when sophisticated TCP accelerations are used.

In these experiments, we use Linux `iperf` [15] to establish 128 TCP connections (with 1500 B packets) to the DUT that runs an `iperf` server. The duration of each test is 15 seconds.

We utilize the Linux traffic control mechanism (`tc`) on the client side to synthetically order the sending packets with a given value of *SLF*. We restrict the sending rate to ~8 Gbps, as forcing a real TCP stack to exhibit a specific *SLF* at high speeds is extremely hard. On the DUT side, we restrict `iperf` to use only one core to clearly delimit the benefits of packet ordering from potential artefacts introduced by parallelism.

Lack of locality makes TCP accelerations ineffective. A variety of TCP accelerations have been devised to mitigate the effects of the increasingly faster NICs' transmission speeds on the relatively stable CPU speed. In this experiment, we show that the most notable of these accelerations, i.e., Large Receive Offload (LRO), is ineffective with low traffic locality.

Ideally, LRO should combine *SLF* consecutive packets of the same flow received at the NIC into a single "super-frame", removing all the Ethernet & IP headers from the merged packets and possibly coalescing redundant packets, such as TCP acknowledgements. However, interleaved packets from different flows prevent LRO from merging consecutive packets which leads to inefficiency of LRO.

The blue boxes of Fig. 1a show that LRO performance is improved significantly when the spatial locality factor increases from 1 to 16, i.e., more consecutive packets in a flow arrive at the DUT. This increase in *SLF* reduces the number of CPU cycles per packet by 69% (from ~10k to ~3k), which shows low traffic locality harms TCP acceleration by LRO. Even without LRO (red boxes in Fig. 1a), the number of CPU cycles per packet decreases by 53% with an increasing *SLF*.

Two explanations for the benefits of spatial locality are:

① **Fewer cache misses.** Ordered packets increase L1 cache hit ratio as common per-flow data structures are fetched only once for all packets. Fig. 1b shows that the number of L1 cache misses per packet decreases by 54% when packets are processed back-to-back. Particularly, we observed an increase in performance for the "__inet_lookup_established" Linux kernel routine. This function performs a lookup in the listening sockets hash table to assign the received packet to the corresponding socket. The improvement is identical regardless of whether LRO is enabled or not and simply depends on having a better packet locality.

② **Fewer CPU instructions per packet.** Since `iperf` uses multiple threads to serve clients' requests, when *SLF* is small, the scheduling routines of the Linux kernel are called more frequently to switch among `iperf` threads. By increasing *SLF*, each thread is able to handle multiple consecutive packets (ideally *SLF* packets) within a single scheduling round of the Linux kernel. Consequently, the number of flow handling routines and executed CPU instructions decreases dramatically with or without LRO enabled (see Fig. 2). LRO further reduces the average number of CPU instructions per packet thanks to the creation of super-frames of packets.

Figure 2: Impact of packet spatial locality on CPU instructions per packet of an `iperf` server, with or without LRO.
(a) 25th (errorbars) and 50th (boxplots) percentile latencies.

(b) 75th percentile latency.

Figure 3: Impact of spatial locality on the forwarding performance of OVS 2.13.9 using the Linux kernel v5.3 data path.

Takeaway. From this experiment we conclude that the performance of today's high-speed networking applications is highly dependant on the spatial locality of the received packets, as this impacts cache-miss ratios and the number of CPU instructions per packet. Based on Fig. 1a, we observe that systems without LRO acceleration but with good spatial locality of packets (i.e., $SLF = 16$) perform *better* than systems with LRO but with poor locality of packets (i.e., $SLF < 5$), making it beneficial to process ordered streams of packets.

2.3 Software Switching Effects

This section quantifies the effects of locality on the performance of the kernel-based Open vSwitch (OVS) [16]; a widely deployed production quality multi-layer software switch. Many Virtual Machine (VM) and container-based cloud platforms (e.g., VMware NSX-T [17], OpenStack [18], Red Hat's OpenShift [19], and Kubernetes [20]) use OVS.

OVS classification pipeline. Upon a packet's arrival, OVS employs a multi-stage classification pipeline. The first stage is a 2^{13} entry Exact Match Cache (EMC) for frequently used flows. This cache uses a 32-bit hash of the packet's header, which can be the Receive-Side Scaling (RSS) hash, as a key mapped to a rule for the corresponding packet. In OVS 2.10, a second classification stage called Signature Match Cache (SMC) was introduced as an experimental feature. This cache stores a 16-bit signature for each flow along with a corresponding 16-bit index into a flow table (with up to 2^{16} rules), a total of 32 bits; hence, it is more memory efficient than EMC, which stores the entire forwarding rule.

If neither of the first two cache levels matches an incoming packet, then that packet is classified by the kernel's Megaflow cache [21]. This cache is based on the Tuple-Space Search (TSS) algorithm [22] that uses more aggressive bitwise wildcarding to aggregate multiple flows into a single match. Finally, a miss in the Megaflow cache results in a packet redirection to the "slow path", where packets traverse a pipeline of OpenFlow tables to derive their corresponding actions.

OVS setup choice. Due to the fact that the EMC is an n-way associative cache (similar to a modern CPU cache), only n out of 2^{13} entries can be used to store any given flow. In OVS version 2.13.9 $n = 2$, implying this cache will likely exhibit high contention even when the number of flows is much smaller than the EMC. Measurements of these OVS caching schemes showed that EMC does not yield the expected levels of performance improvements over the SMC [23]. Specifically, EMC slightly outperforms the SMC *only* with low numbers of flows (< 200), while SMC offers higher performance with more flows [23]. We verified this through our own experiments, hence we disable EMC to achieve higher performance.

OVS experiment. We deployed OVS 2.13.9 on the DUT with a data path through the Linux kernel v5.3 of the DUT. The forwarding behavior is defined by two sets of OpenFlow v1.4 rules with 1k and 10k entries. These rules classify input packets based on their source and destination Ethernet and IP addresses and forward matching packets toward the traffic receiver through the same port (i.e., the Mellanox port of the DUT attached to OVS). Only one rule in each rule set matches the input traffic. We used a Data Plane Development Kit (DPDK)-based traffic generator to inject a trace of 10k User Datagram Protocol (UDP) flows, where each flow consists of 1500-B packets, at the rate of 5.5 Mpps $\approx$ 66 Gbps*. Fig. 3 shows the performance of the kernel-based OVS classifier, focusing on the 25th & 50th (Fig. 3a) and 75th (Fig. 3b) latency percentiles.

Packet ordering greatly benefits OVS's caching scheme. When no particular locality is enforced (i.e., $SLF = 1$), the 75th latency percentile (see Fig. 3b) ranges between 132 μs-343 μs and 126 μs-300 μs for 10k and 1k rules, respectively; while lower latency variance is observed in Fig. 3a for the 25th and 50th latency percentiles. However, both latency and its variance substantially decrease with increasing SLF for both rule sets. The greatest improvement is observed for $SLF \in [20, 24]$, where packet locality results in $2.5 - 5\times$

---

*Similar results occur for TCP packets. With 64-B packets, the effect of packet ordering is less profound, but still relevant.

(a) End-to-end latency.   (b) CPU cycles per packet.

Figure 4: Impact of traffic spatial locality on the packet processing latency and the CPU cycles per packet performance of a NAT and a firewall (with and without rule caching) NFs.

lower 75th latency percentiles, 2× lower medians, and 15-22% lower 25th latency percentiles with negligible latency variance. For higher values of the spatial locality factor (i.e., $SLF \in [28, 32]$), we observe a slight latency increase compared to the lowest attainable latencies shown in this figure. This behavior is not observed in the other experiments in this section, suggesting the limits of packet ordering be studied on a case-by-case basis.

10k rules at the cost of 1k rules. An equally important benefit of this use case is shown in the case of $SLF \in [20, 24]$, where the red and blue boxplots and error bars in Fig. 3 exhibit very similar ranges. This means that packet ordering amortizes the additional cost of a 10x larger classifier (i.e., 10k vs. 1k rules) by making the most out of OVS's caches.

2.4 Network Functions' Effects

In addition to network stacks (§2.2), packet locality may also affect more advanced NFs. To investigate this, we implemented two NFs in FastClick [24], a stateless firewall and a (stateful) Network Address Translation (NAT)*. Unlike §2.2, we allocate two cores per NF with one RX queue per core to show that the benefits of packet locality is not limited to single-core scenarios. We will further discuss the impact of number of RX queues on the DUT performance in §5.1. In these experiments, the traffic generator emulates 10k clients sending a total of 20 million 1-KB UDP packets to the DUT with a total rate of ~50 Gbps (6.2 Mpps) and a given spatial locality factor SLF. Fig. 4 shows the average end-to-end latency and the number of CPU cycles per packet for these two applications.

NAT NF case. We deployed the NAT NF on the DUT. Fig. 4 shows that the end-to-end latency decreases from 103 μs to 74 μs as the spatial locality factor increases from $SLF = 1$ to $SLF = 32$. When $SLF = 1$, some packets are dropped since for each packet, the CPU must wait for the many cycles

it takes to fetch the appropriate NAT table's row from the memory, greatly decreasing the available useful processing time and the capacity of the NF to serve incoming packets. In contrast, when input packets are partially ordered by flow, the NF amortizes the cost of this NAT table lookup over several consecutive packets within the same flow, thus reducing the average processing time needed to serve each packet.

Firewall NF case (without software-based rule caching). We deployed a firewall NF implementing a tree-based Access Control List (ACL) with 20k rules on the DUT. We consider two different variants of this firewall. The first variant assumes *no* rule caching, thus it executes the matching algorithm for each incoming packet. Since all packets of the same flow typically match the same rule, then with an increasing spatial locality factor, we expect a reduction in the frequency of fetching data (rules) from main memory into the system's cache(s). The blue boxes in Fig. 4 show similar trends as in the previous experiment, i.e., an increasing spatial locality factor improves the performance of the firewall in terms of both average end-to-end latency (Fig. 4a) and number of CPU cycles per packet (Fig. 4b).

Firewall NF case (with software-based rule caching). The second variant of this firewall NF implements a simple in-memory rule cache. This cache stores the hash of the last served packet and the matched rule. For each incoming packet, the firewall calculates the packet's hash value, and if it is the same as the entry in the cache, then it assumes that the packet will match the same rule as the previous packet. However, if after executing the rule the new packet does not match the rule, then the cache will be updated with a new matching rule and a new packet hash. The green circles in Fig. 4 show faster convergence to the minimum values compared to the firewall *without* caching as the firewall's cache matches an increasingly large fraction of input packets (i.e., $SLF - 1$ packets for a given SLF) without invoking the firewall's classifier.

Packet spatial locality analysis. Looking closely at the per-packet CPU cycle curves shown in Fig. 4b, we note that the

---

*We also deployed a chain of NFs on the DUT as a complementary experiment in Appendix A.1
Figure 5: Impact of spatial locality on the number of L1 misses per packet for a Firewall (w/o caching) and NAT NF.

data fits an equation of the form $cost = \alpha * (1/SLF) + \beta$, where β is the CPU cost of processing the data that has already been accessed and is in the cache, hence it is the asymptotic limit when SLF is large. In contrast, $\alpha * (1/SLF)$ is a weighted version of the cost of getting the data that can be shared, e.g., when $SLF = 2$, the cost per packet is amortized over two packets.

In the case of the NAT, when $SLF > 1$ the main cost is the lookup of the appropriate replacement values in the NAT table and this lookup only has to be done once for the first packet, hence $\alpha \approx 1$ times the cost of this lookup. In the case of the firewall, we expect that for a given number of firewall rules F, $\beta \propto \gamma * F$ when the firewall rules cannot be cached (i.e., when the rules cannot fit into the cache), hence the firewall rules have to be repeatedly loaded and hence the cost cannot be shared (i.e., $\alpha \approx 0$). However, we see that this is not the case in Fig. 4, as an application still benefits from processor-based caching of the data even *without* software-based rule caching.

Serving packets at the speed of L1 cache. We now highlight the fundamental role played by core-specific L1 cache in enhancing the performance of the above NFs. To measure cache-related events, we utilized the Linux `perf` tool during the execution of the experiments shown in §2.4. Since the NFs' data size (NAT table and firewall rules) are smaller than the LLC and L2 capacity, we see almost no LLC and L2 misses; hence, the reduction in the number of CPU cycles is mostly due to better utilization of the L1 cache.

Fig. 5 shows the effect of locality on the number of L1 cache misses for both the NAT and firewall experiments. In both cases, we observe a substantial decrease in the number of L1 cache misses. Our analysis reveals that we can observe the effects of ordering even on the L2 and LLC misses by deploying a memory-intensive NF (e.g., Deep Packet Inspection (DPI)) or a chain of multiple NFs on the DUT (Appendix A.1). Our results demonstrate that better utilization of core-specific caches is the key for increasing the NFs' performance *and* ordering packets minimizes cache misses.

2.5 Summary

In this section, we explored the effects of spatial locality of network data by conducting experiments across Linux network stack and DPDK-based stateless & stateful NFs at various levels of a system's software stack. The common denominator of this study is that packet ordering greatly increases the utilization of a server's memory hierarchy (mostly CPU caches), which in turn results a substantial improvement in key performance indicators, such as latency, throughput, and CPU utilization.

We leverage these insights to design a system that vertically (i.e., hardware to application layer) exploits the benefits of packet ordering (see §4) and demonstrate complementary results using additional real world applications (see §5). Before this, we investigate whether today's Internet traffic exhibits a low or high spatial locality factor (see §3).

3 Packets Order in Real-world Traffic

This section analyzes a trace from our organization (i.e., a university) to understand the spatial & temporal locality in realistic traffic (§3.1) and explores opportunities to increase traffic locality by reordering packets (§3.2). Our analysis shows that >60% of the packets belonging to a flow are interleaved with packets of other flows, hence non-ideal for high-speed packet processing (based on §2). Moreover, today's networking trends further exacerbate this – as novel congestion control mechanisms (e.g., BBR [25], Timely [26], HULL [27], and Carousel [28]) advocate pacing packets to fight "bufferbloat", i.e., keeping queue occupancy in routers' buffers as low as possible. Even the built-in self-clocking of traditional TCP congestion control mechanisms [29], which inherently spreads packets out over time to avoid congesting a link, is harmful to cache-optimized high-speed network communication. In §4, we advocate rebuilding per-flow traffic bursts as close as possible to the servers that process them.

Trace statistics. We captured 28 min of traffic from our campus to & from our upstream network provider. The outgoing traffic (i.e., from the campus toward the Internet) had 420 million packets with an average size of 1069.43 B and the incoming traffic (i.e., from the Internet toward the campus) had 378 million packets with an average size of 882.82 B. Fig. 6 shows the TCP flow size distribution for this traffic. In the rest of this document, we refer to the outgoing and incoming traffic as the TX and RX traces, respectively.

3.1 Spatial & Temporal Distance

The performance benefits of packet spatial locality were shown in §2 with the greater the number of consecutive packets belonging to the same flow (i.e., the spatial locality factor), the greater the benefits. Additionally, we concluded that even a small spatial locality factor (e.g., $SLF = 5$) could yield a
Figure 6: TCP flow size distr. of the analyzed trace with a log. x-axis. The RX trace has $\sim$ 4M flows; the min., avg., and max. flow sizes (in #packets) are 1, 63, and $\sim$ 29M, resp. The TX trace is composed of $\sim$ 2M flows; the min., avg., and max. flow sizes (in #packets) are 1, 137, and $\sim$ 68M, resp.

(a) Spatial distance (#Packets). (b) Temporal distance (μs).

Figure 7: Distribution of the spatial & temporal distance for the campus trace. (Note that the x-axis is logarithmic).

significant improvement, as was shown in Fig. 4. However, the improvements depend on the traffic's actual spatial locality. Therefore, in this section, we examine how *unordered* the trace from our organization is. To do so, we calculate the spatial and temporal distance of packets in every TCP flow. *Spatial distance* shows the number of packets between two consecutive packets of the same flow and can be used to assess opportunities to exploit cache memories. The higher the spatial locality, the greater the number of opportunities to increase cache-hit ratios. *Temporal distance* measures the time between two consecutive packets of the same flow and can be used to estimate how long one would have to wait for another packet in order to reorder packets and increase spatial locality. Fig. 7 shows the histogram of these metrics for the campus trace. These results do not consider single-packet flows*, as these metrics are undefined for such flows.

Spatial distance. Fig. 7a shows that the spatial distance of the per-flow packets are larger than one packet in ~60% of the RX trace (without single-packet flows) and ~75% of the TX trace (without single-packet flows) – i.e., there is *at least* one packet between consecutive packets of the same flow. The rate of our campus trace is $\sim$2.2 Gbps, which underestimates the values reported for the spatial distance. In networks with

---

*Based upon the source addresses, we expect that some of these are likely to be part of SYN attacks.
Figure 8: Number of per-flow switches for different batch sizes (selected according to [14]): 32/64 for Linux kernel and DPDK; 256 for VPP; and 1024 for GPU/NIC offload).

higher rates (e.g., multi-tens- & multi-hundred-gigabit rates), the spatial distance would *intuitively* be much larger, which further reduces the locality. As shown in §2, this lack of spatial locality can dramatically degrade performance, up to factor of $3\times$. Fig. 8 shows the number of switches across different flows that an application should theoretically perform when processing different batch sizes of packets. The number of switches can be more than $5\times$ larger when the packets are unordered. Frequent switching could cause detrimental performance events (e.g., context switches and/or cache evictions), the number of which depends on the system's microarchitecture (e.g., cache hierarchy) and the application characteristics (e.g., the type of processing and the size of the per-flow state).

Temporal distance. Fig. 7b demonstrates that temporal distance between consecutive flow packets in a flow is typically smaller than a few tens of microseconds, making it possible to reduce the spatial distance by buffering packets for a short time so that they can be reordered. The potential for reordering of traffic destined/originated to/from two cloud providers is described next.

3.2 Potential of Per-flow Ordering

We identified the top hundred IP addresses of the TCP connections, which appeared in independent flows of the TX trace. From those, we select those of two popular cloud providers, referred to as $Cloud_1$ and $Cloud_2$[†]. We calculated the probability of receiving packets of the same TCP flow within different fixed-size time windows to determine whether by waiting for a short amount of time we can reorder packets to make *per-flow* batches of packets, i.e., regenerate high spatial locality. Additionally, since user-space packet processing frameworks (e.g., DPDK) use a fixed batch size for processing packets (typically 32 for a DPDK-based application), we assume that up to 32 packets per flow can be buffered[‡]. Fig. 9 shows the distribution of batch sizes for different buffering times. These results consider all flow sizes, including single-packet and mice flows which dramatically reduces the size

---

[†]Table 1 (in Appendix A) shows the statistics of these flows.
[‡]In some cases it might be possible to buffer up to ~300 packets, see Fig. 23 (in Appendix A).

Figure 9: Impact of increasing the waiting time on the probability of receiving packets in the *same TCP flow* (i.e., packets going to the same end-host, the same core, and the same application).

of the per-flow batches. Clearly, increased buffering time is positively correlated with receiving more packets in the same flow. However, the statistical properties of traffic (e.g., a cloud service) should be taken into account when ordering packets. For instance, it is possible to make per-flow batches of size 6, even in 32-μs time frames, for 25% of the incoming traffic from $Cloud_1$; whereas 25% of the outgoing traffic toward $Cloud_2$ could only be made into per-flow batches of size 4.

Summary. This section showed that *most* of the flows in a campus trace could benefit to some extent from ordering, as it increases locality, i.e., decreases both spatial and temporal distances. However, the improvements depend on the traffic characteristics and type of service. Ordering of larger flows can potentially lead to much bigger improvements (see the tails of the box plots in Fig. 9). Therefore, a cloud provider/operator might only apply reordering to specific services and/or tune the waiting time based on the Service Level Objective (SLO) and the flow rate.

4 The Reframer Design

As we have shown in Section 2, receiving unordered packets leads to high cache misses and more CPU cycles per packet, which increases the cost of packet processing in networking devices. This section presents our proposal to achieve increased end-to-end data locality (both temporal and spatial) of packets in each flow. Our solution maximizes locality and is compatible with today's trends in Internet congestion control paradigms that pace packets. We leverage the idea of briefly buffering, delaying, and reordering the (possibly paced) incoming packets to increase spatial locality for network traffic. As a result, Reframer pays the imposed price of receiving paced packets only one time at the beginning of a NFs and applications chain instead of allowing every single NF pays that for itself. Reframer is developed as a *software* solution that uses CPU cycles to classify flows and create batches with higher locality. Following the trend of Network Functions Virtualization (NFV), advantages of software network functions like Reframer include more flexibility, faster development cycles, and nearly no resource limitation

(e.g., number of per-flow queues) in comparison to hardware alternatives. On the other hand, similar to many networking software systems, the main design challenge is efficiency in terms of both time and space complexity: one needs to strike a delicate balance between the complexity of the reordering procedure, which *consumes* CPU cycles, and the gains at the application/NFs, which *saves* CPU cycles; Hence, it is crucial for Reframer to employ an optimized data structure that takes a short time and space for reordering packets regardless of incoming packets rate and the number of concurrent flows. With Reframer, the incoming packets are efficiently buffered and reordered and then delivered to their destinations. Fig.10 shows the operation of Reframer when a stream of packets belonging to three flows (i.e., green, blue, and brown) arrive at the Reframer.

Flow classification. Reframer maintains two main data structures to reorder packets: a *flow classification table* and a *flush list*. For each flow, the flow table stores the timestamp (TS) when the first packet of that flow has been added to the batch of that flow. It also stores a pointer to the list of the buffered packets for that flow. The flush list is a double-linked list that stores flow identifiers sorted by timestamp described in the flow table. Reframer updates all these data structures in constant time for a variety of operations: buffering of a packet in the flow table (when a flow entry already exists), adding/removing flow identifiers to/from the flush list, finding the oldest flow identifier, and emitting a batch of packets. Only insertion of new flows in the flow table is not performed in constant time because of the cuckoo-hash table. Additionally, Reframer stores only a few bytes of metadata per flow that allows CPU cores to work at the speed of L1 and L2 caches.

In case the number of packets in the flush list meets a configurable limitation (*maximum burst size*), Reframer passes the batch to the scheduler.

Buffering Time. The flush list can buffer flows for a maximum amount of time, which we call the *buffering time* (T_{buff}). The optimal buffering time mostly depends on two parameters: (*i*) flows' average throughput and (*ii*) the end-to-end latency between a Reframer instance and the destination. The former parameter affects the possibility of receiving multiple packets of the same flow in a short time window. For instance, the inter-arrival time of 1000 B packets is 8 μs at 1 Gbps and Reframer can rebuild a per-flow batch with up to 8 packets by buffering packets for 64 μs. The latter parameter sets the upper bound for the buffering time., i.e., a higher end-to-end latency provides more flexibility to wait for packets. It is possible to adjust buffering time by automatically calculating both of these parameters; However, in the current version of Reframer, it should be configured manually by an operator.

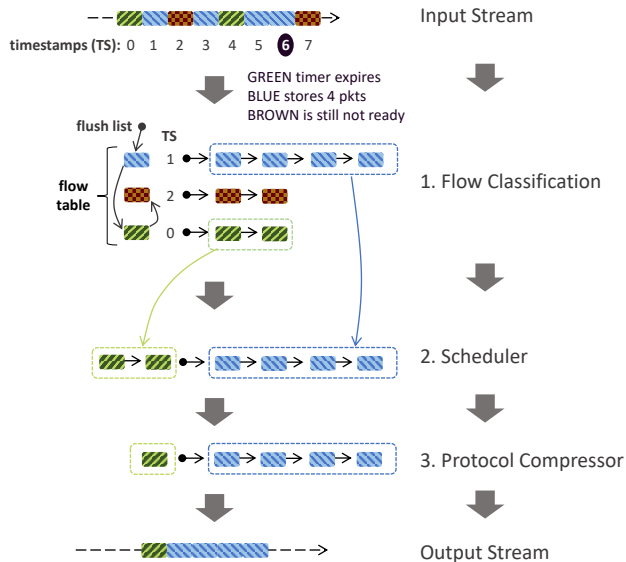
Reframer collects additional information to track its efficiency, i.e., (i) it measures the amount of time that flows were being delayed without actually receiving more packets, and (ii) it records the average amount of packets per batches. These statistics could potentially enable Reframer to fine-tune


Figure 10: Reframer consists of 3 components: (*i*) a classifier arranges input packets to a flow table, (*ii*) a scheduler flushes flows from the table upon a timeout or burst-size, (*iii*) a compression module coalesces packets to eliminate redundancy.

the buffering time by finding the sweet spot between these two statistics for each application.

Priority. When either the flow classifier informs the scheduler of a full-size batch that is ready to be forwarded or the flush list contains flows reaching the buffering time, the scheduler computes an ordering of the batches based on some configurable *priorities*.

The oldest batches in the flow table are extracted from the head of the flush list. The scheduler resets the per-flow data entries upon emission of the corresponding batches.

In the example shown in Fig. 10, we assume the maximum batch size is 4 packets and the maximum buffer time is equal to 6 time units. At time $t = 7$, Reframer receives the fourth packet of the blue flow and at the same time the buffering time of the green flow expires since the first packet was received at time 0. Both batches are handled by the scheduler for transmission. Reframer's scheduler supports a variety of priority models for ordering batches ready to be sent:

Shortest flow first prioritizes mice over elephant flows.
Oldest flow first prioritizes older over newer flows with respect to the timestamp of the first packet; and
Oldest flow in the queue first prioritizes older over newer flows with respect to their waiting time in the queue.
We envision a tailor-made priority model based upon the network operator's SLOs.

Compressor & Output. Before leaving the Reframer, each batch of packets of the same flow passes through a per-protocol optimizer, e.g., multiple TCP ACKs are coalesced if all packets are in order between ACKs. In the future, we will also look at payload coalescing if the MTU allows it.

Reframer supports an integrated *"bypass"* mechanism. Thus, Reframer allows an operator to define class(es) of traffic that should not be reordered by Reframer based on any given field of the packet (e.g., IP DSCP field). We implemented the obvious case of TCP SYN, as a TCP SYN will never be followed by other packets; therefore, a SYN is never delayed. Additionally, in §5.3 we will show that bypassing mice flows may increase the benefit of Reframer because the possibility of receiving multiple packets of the same mice flow in a period of T_{buff} is low and it is not worth to delay such packets. However, in this work, we have not implemented a heavy hitter detection module, which is left for future optimization and it is not discussed here.

Reframer Implementation. We use FastClick [24] to build a Reframer prototype, which enables many placement scenarios at high speed as will be shown in §5. The classification and flow-state management is handled by its MiddleClick [30] extension, thus the code is only thousand lines long[*].

5 Reframer Evaluation

This section assesses the feasibility and performance of Reframer in increasing the temporal and spatial locality of a stream of traffic by briefly buffering and reordering packets. We evaluate performance at both *per-packet* and *per-flow* granularity in two scenarios: (*i*) to improve the per-packet processing throughput of an NF service chain and (*ii*) to reduce the Flow Completion Time (FCT) of TCP traffic streams served by an HTTP web server. Our results show that the NF chain throughput can be increased by ~84% and the HTTP flow completion times be decreased by 100s of *milliseconds* by simply delaying packets by few 10s or 100s of *microseconds*. Specifically, this section answers the following key questions about the opportunities and challenges in reordering packets: (*i*) *Can Reframer increase the packet processing throughput of an NF chain by increasing the traffic locality of a real-world traffic trace (§5.1)?* (*ii*) *How do the Reframer benefits vary depending on where it is deployed (separate or same server as the application, and then on a CPU core or a SmartNIC (§5.2)?* (*iii*) *How can Reframer handle latency-sensitive traffic (§5.3)?* (*iv*) *Can Reframer reduce the flow completion time of an HTTP web server (§5.4)?*

Testbed. We use the testbed presented in §2.1, running an NF service chain of the NAT and the Firewall presented in §2.2 augmented with a router and a flow statistic NF. First, we place Reframer between the traffic source and the DUT, running on a dedicated Intel Xeon E5-2667 CPU clocked at 2.3 GHz and 128 GB of RAM at 2133 MHz. This machine has two Mellanox ConnectX-6 NICs. While this introduces the cost of a supplementary machine, it gives us an understanding of the *maximum* performance achievable when processing the analysed traffic traces.

---

[*]The source code is available at: https://github.com/hamidgh09/Reframer
Figure 11: Traces characteristics - the X-axis is the number of multiples of our campus trace played in parallel

Workloads. We use two different types of workloads in our experiments: (*i*) *per-packet experiments on the NF chain* and (*ii*) *per-flow experiments with the HTTP web server*. The **per-packet experiments** are based on our campus traffic trace described in §3 with millions of flows in total, a throughput of ~2.2 Gbps, and an average packet size of ~1 KB. To evaluate Reframer with a higher traffic throughput, we split the traffic trace into 32 consecutive windows, each of 20 seconds, and we replay them in parallel from our traffic generator. When splitting the trace, we rewrite the flow identifiers so that any two windows do not have any flow in common (which would otherwise increase the traffic locality of the original trace). Figure 11 shows the number of flows and throughput when running a number of parallel trace segments. For the **per-flow experiment with the HTTP server**, we generate HTTP requests of 1MB files from 4096 clients using WRK [31] towards an NGINX web server.

5.1 Packet-Level Experiments (NF Chain)

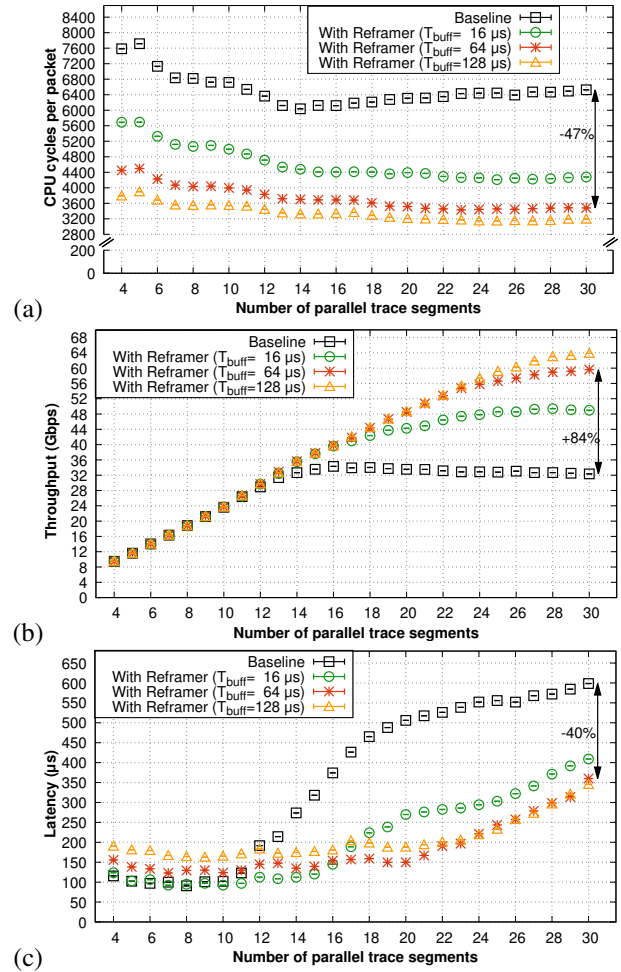
In this experiment, we show that (*i*) Reframer is effective in increasing the spatial traffic locality (i.e., higher *SLF*) of our real-world traffic trace and, consequently, (*ii*) increasing the throughput of an NF chain. Since the trace is replayed, we focus on *per-packet* metrics (e.g., CPU instructions, latency) and the throughput of the NF chain. The NF chain consists of a Flow Statistic Tracker→Router→Firewall→NAT chain, all implemented in FastClick [24] using state-of-the-art NF elements and DPDK [32] for I/O. We install 10k rules into the firewall and 200 different routes into the router elements. We deploy the chain in a run-to-completion model and we consider it as the *Baseline* in all packet-level experiments. To measure the impact of Reframer, we compare the NFs chain performance *with* and *without* deploying a Reframer instance in front of the chain on an external server. Note that the latency is end-to-end in all the experiments which means it *includes* the time spent in the Reframer buffers. In this experiment, 8 CPU cores are assigned to the NFs chain with 8 RX queues on the NIC (one queue per core). The NIC uses RSS to map traffic among queues. We evaluate alternative deployments with Reframer co-located with the NF chain in §5.2.


Figure 12: Performance of Reframer versus a baseline NF with increasing load when processing a real trace: (a) CPU cycles per packet, (b) Throughput, and (c) Latency.

Figure 12 shows the effectiveness of Reframer in improving the performance of the NF chain for different workloads (load is expressed as the number of parallel trace segments). At all loads, in Fig. 12(a), we see a substantial decrease in the number of CPU cycles when using Reframer. The reason is the increase in spatial locality from an average of ~1.2, i.e., near the minimum possible spatial locality, to an average of ~1.9, ~2.9, and ~3.3 at the output of the Reframer with $16\,\mu s$, $64\,\mu s$, and $128\,\mu s$ of buffering times respectively. Fig. 12(b) shows that at high loads, throughput continues to scale well for $T_{buff}= 64\,\mu s$ and $128\,\mu s$, up to ~64 Gbps (a 84-100% improvement) while the throughput peaks at ~48 Gbps for $T_{buff}=16\,\mu s$. In contrast, the baseline throughput peaks at ~33.6 Gbps and then falls - as the DUT cannot keep up. Fig. 12(c) shows that at low loads, the end-to-end latency is roughly the baseline latency plus T_{buff} when using Reframer. However, we see the Reframer benefit appears as the load increases to maximum capacity of the NFs chain. We discuss and evaluate how to reduce the additional latency introduced by Reframer in §5.3.
Figure 13: Reframer vs Baseline with various number of hardware RX queues (up to the max. supported by the NIC).

(a) DUT throughput.   (b) Reframer capacity.

Figure 14: Maximum throughput of Reframer and DUT with different number of cores.

High number of RX queues has small impact on the DUT throughput. We repeated the above experiment with 30 parallel trace segments and various numbers of RX queues on the DUT in a range of 8 to 500 (which is the maximum possible number of RX queues on the DUT's NIC). We preserve the total number of descriptors around 8192 by setting per queue descriptors to $max(32, 2^{14-\lceil \log N \rceil})$ where N is the total number of RX queues. In this experiment we show that by increasing the number of RX queues the average spatial locality increases from ~1.2 to ~2.5 without Reframer. However, despite the improvement in the traffic locality, Figure 13 shows only a slight increase in the maximum throughput of baseline. The main reason is, having hundreds of RX queues leads to more empty polling in the DUT which is costly and negatively affects the performance. It is worth noting that, fetching incoming packets from RX queues is hardware-specific and depends on the data structures that NICs are using to process incoming packets; hence, optimizing algorithms and data structures in future NICs may lead to better results. However, discussing the future road map of NICs is out of scope of this paper. On the other hand, when Reframer is located between the traffic source and DUT, increasing the number of DUT RX queues has a negative impact on the throughput because incoming packets are already sorted and classifying flows in different hardware queues does not increase packets' locality. So we set 8 RX queues (one per core) for DUT when Reframer exists in the network. Finally, we see 53% more throughput with Reframer
(a)
(b)

Figure 15: Impacts of Reframer when collocated with the NF chain: (a) Cycles per packet and (b) Throughput.

vs. using hundreds of RX queues for the baseline case.

Packets' locality benefit persists with various number of DUT cores. We also show that Reframer benefits do not depend on the number of DUT cores. To do so, we measured the maximum throughput of DUT by running the experiment with various number of cores assigned to DUT. Reframer's buffering time is set to 128 µs in all cases. Figure 14a demonstrates that the throughput increase rate is almost the same for different number of cores.

Reframer scales almost linearly with the number of cores. As we discussed in §4, Reframer benefits from an optimized data structure to classify, order, and flush packets in a constant time. Our stress test reveals that Reframer is able to handle up to 28 Gbps with only *one core*. Here, we increase the offered load gradually until we see ~1% packet drops in Reframer. Figure 14b shows that Reframer's capacity increases *almost linearly* when increasing the the number of cores.

5.2 Same-Server Deployment

In the previous section, we showed that deploying Reframer on a dedicated server increases spatial and temporal locality, ultimately resulting in significant performance gains. In the following experiments, we evaluate deploying Reframer on the same server where an application is running. Using the same NF chain (Baseline) as previously, we consider two deployments: (*i*) chaining Reframer with the NF chain, i.e., the entire chain running to completion on the same CPU cores (referred to as *in-chain* deployment), and (*ii*) deploying Reframer on a SmartNIC.

**In-chain deployment.** We evaluate the performance of Re-

Figure 16: Impacts of Reframer when collocated with the NF chain: (a) Average latency and (b) 99.9th percentile latency.

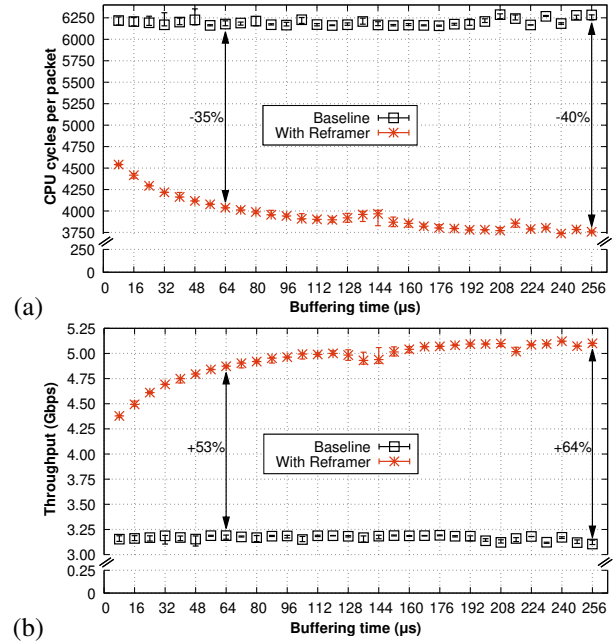

Figure 17: Impact of Reframer when offloaded into a Smart NIC which precedes the NF chain: (a) Cycles per packet, (b) Throughput. Latency is given in Appendix A.2

framer for the *in-chain* deployment versus the *baseline* for different buffering times. Generally, increasing buffering time in Reframer will lead to more packet locality, since it increases the possibility of receiving more packets of the same flow; Hence, we see a considerable increase in the DUT throughput and reduction in the end-to-end latency. Fig. 15 shows that by placing Reframer right before the service chain, the number of cycles per packet decreases with increasing buffering time while throughput increases by 60% when Reframer buffers packets for 64 μs. To evaluate the impact of Reframer on the packets end-to-end latency, we restrict the incoming packet rate to ~30 Gbps which is less than the maximum capacity of DUT in the baseline mode. In Fig. 16 we can see the average latency is reduced by 46% with T_{buff}=64 μs. Additionally, Reframer improves the tail latency by ~26% even when it is collocated with service chain on the same server. In this experiment, latency benefits start to fade gradually from a specific buffering time because the cost of delaying packets surpasses the processing speed-up. The baseline numbers are mostly the same for all x axis values because we have no buffering in baseline mode. The fluctuation in baseline values is inevitable because DUT cores are at a maximum load.

SmartNIC deployment. As a proof-of-concept deployment for offloading Reframer into a NIC to save CPU core resources on the server, we deployed Reframer on two ARM cores of a Mellanox Bluefield SmartNIC – equipped with 16×64-bit Armv8 A72 cores and two 100 Gbps ports while the NFs chain works on a single CPU core. Fig. 17 shows improvements in throughput similar to the in-chain deployment. We discovered that the performance using a single ARM core

was limited by the current Mellanox drivers for the cards, a constraint/limitation confirmed with Mellanox.

Flow-oblivious batching is highly suboptimal. We also compare Reframer with a Batchy-like [14] implementation written in FastClick. Batchy is a state-of-the-art packet processing system that buffers packets in a *flow-oblivious* manner at multiple locations in an NF chain, i.e., Batchy does not create bursts of packets from the same flow but mix all flows that must be processed by the same NF element. We observe that Batchy improves the throughput of the chained NFs by 4%, whereas Reframer improves throughput by 48%. These results corroborate our analysis in section (§2), where we showed how detrimental it is to process streams of packets that are highly interleaved between different flows as opposed to per-flow batches.

5.3 Latency-Sensitive Flows

In our previous experiments, Reframer delayed all types of packets for a T_{buff} interval, possibly increasing the FCT or packet processing time of short flows. We argue that an operator could explicitly tag which traffic classes should be delayed to improve application throughput. To evaluate the impact of delaying only large flows, we ran an experiment similar to the one described in §5.1, but we explicitly flag only large flows so that Reframer can batch them while bypassing the unflagged packets and show the results for increasing number of parallel trace segments in Fig. 18. Compared to the case where all flows are delayed, the throughput of
Figure 18: Reframer provides differentiated services by prioritizing small flows over large flows which are bypassed.

the NF chain slightly decreases (between 0% and 4% according to the number of parallel trace segments), while the latency of the packets belonging to the small flows align with the best of the baseline (at low loads) or the latency of Reframer minus the buffering delay (at higher loads). Somewhat surprisingly, Reframer achieves *lower latencies* than the baseline for small flows across *all* traffic loads by simply delaying and reordering only large flows. We leave the detection of heavy-hitters, for instance detecting which flows could have generated multiple larger bursts, as future work.

5.4 Flow-Level Experiments (HTTP Server)

In this experiment, we evaluate Reframer to assess its impact on a web server application using TCP connections to dispatch files of 1MB to a set of 2048 clients continuously fetching files. By controlling the rate and number of clients' requests, we are also able to substantially increase the throughput of the test and exploit the 100G NIC interfaces. To simulate 4096 independent clients with more realistic latencies, we place a machine in-the-wire that delays packets in per-flow queues by ~10 ms±~2 ms. Hence, each connection exhibits slightly different delays, for an average ~20 ms delay. The focus of this experiment is on flow-level metrics, with the goal to check whether (*i*) Reframer improves the FCT of the dispatched files and (*ii*) the buffering delays cause any troubles to the underlying congestion control mechanism (i.e., TCP Cubic). We compare the *baseline* against Reframer. We selected NGNIX 1.14 as the web server running on 16 cores of the DUT, while Reframer runs on a dedicated NF machine using 6 cores. Reframer reorders packets in both directions, aggregates TCP ACKs from the client to the server, and eventually reorders out-of-order TCP packets. Fig. 19(a) shows that Reframer increases the application throughput by 20%. The observed improvements are due to the increase in spatial locality from 1.25 to 14. Fig. 19(b) shows that despite introducing delays in the order of microseconds, Reframer *reduces* FCT of TCP connections by fractions of a second (from 3.4 s to 3.1 s). ACK coalescing accounts for ¼ of the throughput improvements but does not affect the FCT.

6 Related Work

Batching. Previous efforts [14, 24, 33–35] have shown the importance of processing entire batches of packets rather than individual packets (not necessarily belonging to the same flow) in order to amortize the costs of the interrupts in the NF processing system (e.g., Batchy [14], SCC [35]). Our work is orthogonal to these approaches because Reframer improves the performance of a server application in a "transparent" way, e.g., by reordering packets on the NIC or before being sent to the application. Moreover, existing packet processors do not increase the traffic locality at the per-flow level, which we show to be critical to achieve high performance in §5.2.

Traffic coalescing. Receive Side Coalescing (RSC) [36] aka LRO accelerates TCP processing by merging consecutive packets of a TCP flow into a single frame. Unfortunately, as shown in §2.2, hardware-based LRO breaks as soon as packets are interleaved. Similarly, the software implementation of LRO in the Linux kernel, called Generic Receive Offload (GRO) [37], suffers from the same problem.

Packet schedulers. We distinguish between *hardware* and *software* packet schedulers. Hardware packet schedulers typically try to realize different approximations of universal schedulers mapping packet ranks to the available queues on the hardware (e.g., [38–43]). Another set of hardware packet schedulers (e.g., [44–52]) focus on network-level optimization in datacenters (e.g., minimize traffic congestion). None of *all* these works have explicitly looked at the possibility of batching and scheduling packets to increase traffic locality at

the per-flow level. For instance, pFabric [44] would *nullify* any high traffic locality by purposely interleaving flows.

Stardust [53] is a hardware-based fabric architecture for datacenter scale networks. Stardust classifies packets per destination and chops them into bounded-size cells. This technique enables Stardust to send chops of packets in a burst, which potentially minimizes the cost of processing them at the destination. However, based on our understanding, Stardust's cells are flow-agnostic, whereas Reframer improves the performance of NFs and applications by increasing the traffic locality at the per-flow level. Moreover, Reframer *purposely* delays packets, which is the *pivotal* aspect of our proposed solution.

Software-based packet schedulers (e.g., [30, 54–61]) operate at the CPU level with the goal of dispatching the incoming flows (or coflows) of traffic to the different cores on the machine running packet processing operations. Also in this case, *none* of these approaches have explicitly looked at the impact of traffic locality on the performance of the applications receiving the packets.

To summarize, existing scheduling schemes do *not* take into consideration the impact of per-flow traffic locality. In contrast, Reframer schedules and prioritizes bursts of flows using a variety of policies while exploiting opportunities for packet coalescing and increased traffic locality.

TCP accelerations. AccelTCP [62] and Tonic [63] are dual-stack solutions that offload or generalize stateful TCP operations to NICs in order to simplify the end host stack. Such operations include connection setup and teardown as well as connection splicing that relays packets of two connections entirely within a NIC. To the best of our knowledge, *none* of these works explicitly aim to increase per-flow traffic locality.

7   Conclusions

This work unveiled the importance of packet ordering on many applications, specifically NFs and TCP applications. We showed that receiving traffic by bursts of packets of the same flow could improve a server's performance by a factor of $3\times$ as opposed to receiving packets of interleaved flows. Analyzing realistic traffic, we found that by slightly delaying traffic, even by only 64 μs, one can potentially re-build bursts of packets. We then described Reframer, a software NF, capable of re-building bursts at 28 Gbps with a single core, and scalable to 100 Gbps with a few cores. We showed Reframer is still highly beneficial when deployed as part of an NF chain, while bringing performance improvements to the server and its services. We believe this paper will spur new research around the delicate interaction between congestion control mechanisms and cache-based optimizations. It also calls for further potential improvements, e.g., decreasing the number of frames by coalescing payload or realizing Reframer in hardware.

A Supplementary Material

This section provides some additional material for this paper.
A.1 Deploying a chain of NFs

In addition to experiments discussed in §2.4, we deployed a chain of network functions on the DUT as a complementary experiment. In this test, we connected a Router, a NAT, a

(a) End-to-end latency in µs.

(b) L1 misses per packet.

(c) L2 misses per packet.

(d) LLC misses per packet.

Figure 20: Impact of packet order on the performance of a Router→NAT→Firewall→FC chain of NFs.

firewall, and a Flow statistics counter (FC) in a row, as a chain of NFs. The DUT uses 4 CPU cores to serve the packets and it is implemented in a run-to-completion model to exploit the parallelism on the processors. All the other configurations are similar to §2.4.

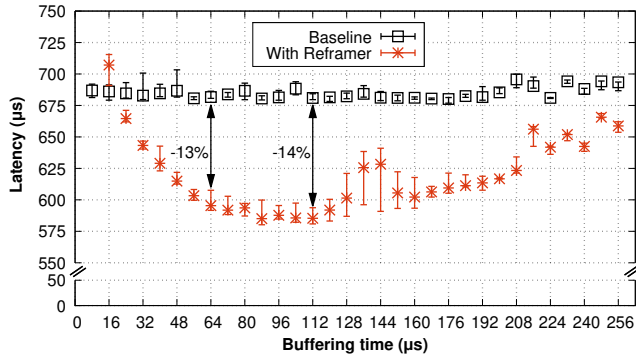
Since the deployed chain is both CPU and memory intensive, the scale of CPU cycles per packet and the end-to-end latency are higher in compare to individual NAT and firewall experiments in §2.4. However, the results in Figure 20 confirm that, regardless of the complexity of the implemented


Figure 21: Latency of Reframer when offloaded into a Smart NIC which precedes the NF chain.

Figure 22: Impact of increasing the waiting time on the probability of coalescing Transmission Control Protocol (TCP) ACKs. (The figure is intentionally scaled to enhance the visibility of the first to third quartiles.)

NFs, ordering the packets has a significant impact on the DUT's performance.

Similar to §2.4, the fundamental reason of such enhancement is efficient utilization of system caches. In this experiment, since the DUT needs more data to process a packet, the improvement in cache misses has been extended to L2 and LLC. Figure 20d shows a substantial improvement in terms of number of LLC misses. Note that this improvement is not happening only in LLC. We also can see the same trend (with smaller improvement factors) in L1 (Figure 20b) and L2 (Figure 20c) caches.

A.2 Running Reframer in a SmartNIC

Figure 21 shows the latency induced by the Reframer versus a baseline NF, when deployed on two Arm cores of a Mellanox Bluefield SmartNIC.

A.3 Analyzing the Trace

To perform the analysis, we have used PcapPlusPlus to create a CSV file composed of useful fields. Then, we split the 62-GB file to per-flow CSV files via Spark. Finally, we use Python data science libraries (e.g., Pandas and NumPy) to calculate the probability of receiving different batch sizes

Figure 23: Impact of increasing the waiting time on the probability of receiving packets with the same TCP flow.

within different time windows. Listing 1 shows the python code used to process each flow.

ACK coalescing. Fig. 22 shows the potential improvement from TCP ACK coalescing in the campus trace. We calculated the distribution of the number of per-flow packets with enabled TCP acknowledgment flag (ACK) within a time frame.

```python
import pandas as pd
import numpy as np

# Calculate the size of ordered batches for each flow
# based on the input window size (ws)
def process(flow,ws):
    # Getting the timestamp of packets in a flow
    ts = flow['ts'].to_numpy()

    # Initialize variables
    batch_size=1
    i=1
    ordered_size=np.empty((0))
    threshold=32

    # Check the size of flow
    if ts.size == 1:
        # Add the batch_size to the array of ordered_size
        ordered_size = np.append(ordered_size,batch_size)
    else:
        # Sort the timestamps
        sorted_ts = np.sort(ts)
        # Start from the first packet of a flow
        base_ts = sorted_ts[0]

        # Continue while there is still more packets
        while i < sorted_ts.size:

            # Increase the size as long as the next packet
            # arrives before the end of the window size
            if sorted_ts[i] - base_ts < ws :
                batch_size = batch_size + 1

            # If the size of the batch is larger than
            # the threshold or the next packet of the flow
            # comes after the end of the window size.
            # The batch size and the time counter,
            # we should stop the time counter. Stopping
            # the counter means that we start the counter
            # again with the next packet. Also, we update the
            # beginning of the window size with the timestamp
            # of the newly arrived packet.
            if (batch_size >=threshold) \
                or (sorted_ts[i] - base_ts >= ws):
                # Update the beginning of the window size
                base_ts = sorted_ts[i]
                # Add the batch size to the array
                ordered_size = np.append(ordered_size,batch_size)

                # Reset the batch size
                if batch_size != 1:
                    batch_size = 1
                    i = i + 1
                    ordered_size = np.append(ordered_size,count)
    return ordered_size
```

Listing 1: Python function used to calculate the size of the per-flow batches.

Table 1: Flow statistics per Internet Protocol (IP) address of two popular cloud providers.

Abstract

Request latency is a crucial concern for modern cloud providers. Due to various causes in hosts and networks, requests can suffer from request latency anomalies (RLAs), which may violate the Service-Level Agreement for tenants. However, existing performance monitoring tools have incomplete coverage and inconsistent semantics for monitoring requests, resulting in the difficulty to accurately diagnose RLAs.

This paper presents BufScope, a high-coverage request event monitoring system, which aims to capture most RLA-related events with consistent request-level semantics in the end-to-end datapath of request. BufScope models the datapath of request as a buffer chain and defines RLA-related events based on different properties of buffers, so as to *end-to-end monitor* the root causes of RLA. To achieve *consistent semantics* for captured events, BufScope designs a concise request-level semantic injection mechanism to make events captured in networks have the victim requests' ID, and offloads the realization to SmartNICs for *low overhead*. We have implemented BufScope on commodity SmartNICs and programmable switches. Evaluation results show that BufScope can diagnose 95% RLAs with <0.07% network bandwidth overhead and <1% application throughput decline.

1 Introduction

With the emergence of cloud-native architecture [1], application-layer requests (*e.g.,* RPC, HTTP, and RESTful requests) become a fundamental component in the cloud [2]. The request latency is the total elapsed time across a request end-to-end datapath, including the application, the end-host network stack and the underlying network. Since request latency directly affects the performance of many distributed applications [3], it has become a crucial concern [4–6] for cloud providers. Besides, request-level information is the tie between the tenants and the cloud providers. For instance, when a request (*e.g.,* search, storage I/O) encounters a surge of latency, the tenant will provide the operators with the request-level descriptive information to diagnose the anomaly [7].
